# Preface

---

This manual is part of the *Aleph Programming Language Series*, a multi volume set that describes the programming environment of the **Aleph** system. The entire set contains 4 volumes :

**Volume 0 - Aleph Installation Guide** is the distribution installation manual.

**Volume 1 - Aleph Programmer Guide** is the first volume of this set. It is both an introduction and an advanced guide for the the developer.

**Volume 2 - Aleph Library Reference** is the second volume of this set. It is a complete description of the Aleph standard library.

**Volume 3 - Aleph Cross Debugger** is the third volume of this set. It is a reference manual to develop and debug Aleph programs.

**Volume 4 - Aleph C++ API** is the fourth volume of this set. It is a reference manual of the C++ Application Programming Interface (API).

## The Aleph programming language

**Aleph** is a multi-threaded functional programming language with dynamic symbol bindings that support the object oriented paradigm. **Aleph** features a state of the art runtime engine that supports both 32 and 64 bits platforms. **Aleph** comes with a rich set of libraries that are designed to be platform independent. **Aleph** is a free software. A flexible license has been designed for both individuals and corporations. Everybody is encouraged to use, distribute and/or modify the aleph engine for any purpose.

## Features

The **Aleph** engine is written in C++ and provides runtime compatibility with it. Such compatibility includes the ability to instantiate C++ classes, use virtual methods and raise or catch exceptions. A comprehensive API has been designed to ease the integration of foreign libraries.

- **Builtin objects**  
More than 50 reserved keywords and predicates. Various containers like list, vector, hash table, bitset, and graphs.
- **Functional programming**  
Support for *lambda expression* with explicit closure. Symbol scope limitation with *gamma expression*. Form like notation with an easy block declaration.

- **Object oriented**  
Single inheritance object mechanism with dynamic symbol resolution. Native class derivation and method override. Static class data member and methods.
- **Multi-threaded engine**  
True multi-threaded engine with automatic object protection mechanism against concurrent access. Read and write locking system and thread activation via condition objects.
- **Original regular expression**  
Builtin regular expression engine with group matching, exact or partial match and substitution.

**Aleph** is a core language and libraries. The libraries are a specific set of classes and functions which are structured per application domains. **Aleph** is delivered with a set of standard libraries.

- **aleph-sys**  
The `aleph-sys` library is the system calls library. Standard classes and functions are provided to interact with the running machine.
- **aleph-sio**  
The `aleph-sio` library is the standard input/output. All input/output operations are performed with this library.
- **aleph-net**  
The `aleph-net` library is the networking library. The library is based on the standard *Internet Protocol* and provides various classes to manipulate IP address, client or server sockets.
- **aleph-www**  
The `aleph-www` library is the World Wide Web library. The library provides various classes that ease the development of web applications or CGI scripts.
- **aleph-txt**  
The `aleph-txt` library is the text processing library. The library provides various functions and classes that ease text manipulation. Sorting data, computing message digest and formatting table is among others, features available in this library.
- **aleph-odb**  
The `aleph-odb` library is the object database library. The library provides several objects that can be used to design a database. A client is also provided to directly access the database contents.

**Aleph** provides *extensions*. An extension is a library or an application which is not installed by default. The user selects during the installation process which extension is needed. For example, the static version of the interpreter is an extension.

## Aleph engine

**Aleph** is an interpreted language. When used interactively, commands are entered on the command line and executed when a complete and valid syntactic object has been constructed. Alternatively, the interpreter can execute a source file. **Aleph** does not have a garbage collector. **Aleph** operates with a lazy, scope based, object destruction mechanism. Each time an object is no longer visible, it is destroyed automatically. At this time, the **Aleph** interpreter is unable to reclaim memory with circular structures. This is a well known problem when using a reference count mechanism. In the future, the **Aleph** engine will provide some mechanisms to resolve this problem.

## Flexible Distribution

**Aleph** is a free software. A flexible license model encourages individuals or corporations to use, copy, modify and/or distribute this software. **Aleph** is designed by software professionals. Quality is one the driving force of the development effort. This is reflected in this distribution by the extensive documentation. A large test suite is used to assess the quality of the distribution. Right now, the engine has been successfully tested on most Linux platforms, Free BSD and Solaris.

---

# License

---

**Aleph** is a free software. It can be used, modified and distributed by anybody for personal or commercial use. The only restriction is altering the copyright notice associated with the material. Individual or corporation are permitted to use, include or modify the **Aleph** engine. All material developed with the **Aleph** language belongs to their respective copyright holder.

This program is a free software. it can be redistributed and/or modified, providing that this copyright notice is kept intact. This program is distributed in the hope that it will be useful, but without any warranty; without even the implied warranty of merchantability or fitness for a particular purpose. In no event shall the copyright holder be liable for any direct, indirect, incidental or special damages arising in any way out of the use of this software.

---

# CHAPTER 1

## Introduction

---

This chapter is an introduction to the general organization of the **Aleph** C++ *application programming interface* or API. We start by looking at the various levels of the API and then describes the general presentation of the C++ header files. The reader needs to absorb some materials before being able to write its own class. For the impatient, we recommend to read this chapter and the next one. A simple example is given at the end of chapter 2.

### 1.1 The header files

All **Aleph** API files are structured into several directories, each of them dedicated to a specific functions. All directories are generally located below an **aleph** specific directory or for some distributions under the standard `/usr/include` or `/usr/local/include` directories for a UNIX platform.

- **plt**  
The platform independent header files.
- **std**  
The standard object header files.
- **eng**  
The **Aleph** engine header files.

Additional directories are included. One for each library and extension.

#### 1.1.1 The platform headers

The `plt` directory contains the platform independant headers files. The files are low level functions and should be the last thing to use. Their use will be covered later.

#### 1.1.2 The standard objects headers

The `std` directory contains the standard object headers files. This directory is the primary source of files. It contains the most important header, named **Object**. The **Object** header is covered in the next chapter.

#### 1.1.3 The interpreter engine headers

The `eng` directory contains the interpreter engine header files. This directory is as important as the standard object one. It contains the **Interp** object, which is the interpreter by itself.

## 1.2 Conventions

The general structure of the **Aleph** API rely on various conventions and rules. These rules have been carefully designed to ensure portability accross platforms as well as a smooth support for 32 and 64 bits platforms.

### 1.2.1 Header file extension

All header files use the `hpp` extension. These header files only reference **aleph** functions or classes. If there is one rule to keep in mind, it is this one. **There is no platform header files.** This rule provides the flexibility to design a system which is platform independant. Because of the `Makefile` structure, any attempt to use a platform header will cause a compilation error. If one take a look at the source tree, (s)he will find another header type with extension `hxx`. This type of header are the one which contains the platform dependant headers. However, this type of headers is never exported to the API.

### 1.2.2 Aleph namespace

All functions and classes belong to the namespace `aleph`. This namespace should be used only for software code which is supposed to be part of the **Aleph** distribution. If you plan to develop your own piece of code, please use another namespace.

### 1.2.3 Makefile

There is no particular rules for `Makefile`, unless the software beeing develop is supposed to be integrated into the distribution.

## 1.3 Types, declaration and memory

The basic types used everywhere are defined in the `plt/ccnf.hpp` header file. This file contains also some information about your operating system, the processor type and the software revision. It is strongly suggested to take a look at it. The basic types are defined inside the `aleph` namespace.

```
typedef unsigned char    t_byte;
typedef unsigned short   t_word;
typedef unsigned int     t_quad;
typedef unsigned long long t_octa;
typedef long long        t_long;
typedef double           t_real;
```

The special type `t_size` is determined automatically according to the platform. A 32 bits platform has:

```
typedef unsigned int     t_size;
```

while a 64 bits platform has:

```
typedef unsigned long    t_size;
```

It is by far the `t_size` type which is the most important. This type is automatically determined by your platform configuration. You should almost never use the `int` type, except for resource description. The `long` type is most of the time appropriate and `t_long` required when a 64 bits width needs to be forced. Since most compiler adopt the *LP64* model, the `long` type seems to be a good choice. Note that this header file is automatically included in the **Object** file.

### 1.3.1 Character and strings

The `char` type is the preferred type for a character. The implementation uses the `const char*` for the c-strings. The standard object library provides a **String** class that take care of string manipulation. On the other hand, the basic c-string declaration is inevitable when dealing with literal string. The `t_byte` type is appropriate for *unsigned character*.

### 1.3.2 Memory allocation

We will talk a lot about memory allocation later. At this stage, note that `new` and `delete` are the best way to operate. You should almost never use the low level memory allocation since it might conflict with the *memory tracer* and worse with the shared libraries memory cleanup subsystem. Obviously, call to `malloc` and `free` are prohibited. In fact, these functions are not exported by the API. If an object is generated by a function or method and need to be destroyed, a call to `delete` is the way to go, nothing else will work. **As a matter of facts, the object destruction is a more complex subject, which is detailed in chapter 3.**

---

# CHAPTER 2

## Eval-Apply and functions

---

The *eval-apply* mechanism is the central runtime operation of the **Aleph** engine. Depending on the nature of the form to evaluate, one strategy or another is used to perform the *eval-apply* process. It is interesting to note that a complete program execution is merely an *eval-apply* loop.

### 2.1 Interpreter eval-apply

The **Aleph** interpreter rely on a mechanism called an *eval-apply* loop. For each form being evaluated, the first object evaluation method is called. The returned object is eventually used to apply one or several evaluated arguments. We describe in detail how this mechanism works with various example.

#### 2.1.1 Various eval-apply

There are several kinds of *eval-apply* strategy that are used depending on the nature of the form.

- *add + 1 2*  
This is the simplest form to evaluate. The form consist of a list of objects. The first object is evaluated and the rest is transmitted to the evaluated object during the *apply* phase. Our first example will cover this type of form.
- *Boolean true*  
This form is an object construction form. Its evaluation is slightly different to the previous one. This type of form is covered in the next chapter.
- *aleph:sys:sleep 1000*  
This form is similar to the first one, except that it uses a qualified name instead of the a lexical name.
- *str:split ":"*  
This form is a method call with argument. It's evaluation is described in the next chapter.
- *println "hello world"*  
This form is a special form. Its evaluation is described in a specific chapter. Forms that uses a reserved keyword are generally special forms. Note that the reserved keywords **const** and **trans** are special, for a special form.
- *+ 1 2*  
This form is a generic operating form. Its evaluation is described in a specific chapter.

### 2.1.2 The simplest eval-apply

The simplest example to consider is the introductory form `add 1 2`. This form consists of three objects. The first one is a lexical object, the second and third are literals. When the form is evaluated several steps are performed. The form is represented by three *cons cells*. The *car* contains the lexical object. The *cdr* points to another *cons cell*, those *car* is an `Integer` object. The *cdr* of the second *cons cell* points to the third argument, those *car* is also an `Integer` object. The last *cdr* is *nil* (null pointer) to indicate the end of the form. This form is automatically built by the **Aleph** reader. During the evaluation process, several operations take place, as described below.

- Evaluates the first object in the form. The object is a lexical object represented by `add`. Such evaluation is done with the interpreter by calling the object virtual method **eval**. In that particular case, the lexical evaluates to a function object.
- Apply the first evaluated object with the rest of the form. For that particular example, the first object has been evaluated as a function object. The virtual **apply** method is called with the *cdr* of the form. The `apply` method returns the result of such application. In that particular case, the `add` function method returns an `Integer` object, those value is 3.
- What happen inside the **apply** method is implementation dependent. However, for that particular example, the `add` method evaluates each argument object, check that they are valid integers, compute the sum, and returns a newly created integer object with the result.

This simple example illustrates the fundamental mechanics of the **Aleph** engine. Note that the process we have described here is simply the evaluation process of a *cons cell*. We will come back later on this.

### 2.1.3 Runnable object

The **aleph** interpreter is a *runnable* object. A *runnable* object is a special object that carry several methods. Our first example do not need it, but the object is part of the API. A typical use of the *runnable* object is within the `println` builtin function (special form). Such function get the standard output stream from the *runnable* object. The *runnable* object is defined in the standard library as **Runnable**.

### 2.1.4 Evaluation nameset

An *eval-apply* process is done within an *evaluation nameset*. The *evaluation nameset* is the point at which a symbol or an argument is evaluated. The first example does use the evaluation nameset to resolve the symbol `add`. The *nameset* object is defined in the standard library as **Nameset**.

### 2.1.5 Object eval-apply methods

The **Object** class contains several overloaded **eval** and **apply** methods. We are here only concerned with the simple one.

## 2.2 The add function

The C++ implementation of the **add** function declaration is given below. The first argument is the *runnable* object. The second argument is the *evaluation nameset* object. The third argument is the argument list. At this stage of the call, the symbol `add` has been evaluated (we will how later), and the function is called with the last two arguments as a result of an `apply` call.

```

Object* example_add (Runnable* robj, Nameset* nset, Cons* args) {
    // evaluate the arguments in a vector
    Vector* argv = Vector::eval (nset, args);
    // compute the result
    long result = argv->getint (0) + argv->getint (1);
    // generate result
    return new Integer (result);
}

```

As it can be noticed, this implementation is quite simple and will work. Unfortunately, it will also leak, since the argument vector is not destroyed. Note also that an exception might also happen. A perfect implementation should enclose the computation in a *try-catch* block and destroy the argument vector. The complete implementation, ready to compile, is given below, with the appropriate include file and namespace. This example is available in the `exp/api` directory as `Add.cpp`.

```

#include "Vector.hpp"
#include "Integer.hpp"

namespace example {
    // use the aleph namespace
    using namespace aleph;

    // add function implementation
    Object* example_add (Runnable* robj, Nameset* nset, Cons* args) {
        // evaluate the arguments in a vector
        Vector* argv = Vector::eval (robj, nset, args);
        try {
            // compute the result
            long result = argv->getint (0) + argv->getint (1);
            // clean the vector
            delete argv;
            // generate result
            return new Integer (result);
        } catch (...) {
            delete argv;
            throw;
        }
    }
}

```

## 2.3 Putting all together

Once the `add` function has been implemented, it must be registered within the interpreter. There are various ways to do so. The description below uses the standard **Aleph** mechanism with shared libraries. Once the library will be built, it is going to be possible to test the function.

### 2.3.1 Shared library entry point

The first thing to do, in order to create a shared library, is to define a unique entry point that is called when the library is loaded. This entry point takes care of registering the library symbols. The **Aleph** convention uses names in the form of `dli_namespace_library`. The plus (+) and and minus (-) characters are automatically re-mapped to underscore character. For example, the library

aleph-sys has the entry point `dli_aleph_sys`. Our example uses the namespace example, so a valid entry point would be `dli_example` or preferably `dli_example_api`. The entry point must be mapped as a "C" name to avoid *name mangling*. It is also part of the **Aleph** methodology to break the call in two pieces. One is the "C" entry point and the other is the "C++" entry point.

```
#include "Libapi.hpp"
#include "Apicalls.hpp"
#include "Function.hpp"

namespace example {
    // use the aleph namespace
    using namespace aleph;

    // initialize the api library
    Object* init_example_api (Interp* interp, Vector* argv) {
        // make sure we are not called from something crazy
        if (interp == nilp) return nilp;

        // create the api nameset
        Nameset* api = interp->mknsset ("api", interp->getgset ());

        // bind the add function
        api->symcst ("add", new Function (api_add));

        // not used but needed
        return nilp;
    }
}

extern "C" {
    aleph::Object* dli_example_api (aleph::Interp* interp,
        aleph::Vector* argv) {
        return example::init_example_api (interp, argv);
    }
}
```

### 2.3.2 Compiling everything

The compilation is quite simple. The library generation is a little more tricky. The previous example is demonstrated with GCC and assume that the **Aleph** include file are located in the `/usr/local/include/aleph` directory.

```
zsh > g++ -I. -I/usr/local/include/aleph -g
        -fPIC -D_REENTRANT -c *.cpp
zsh > g++ -shared -o libexample-api.so *.o
        -L/usr/local/lib -laleph-eng
```

These commands should work fine. However, depending on your system, some adjustments might be needed. You should look at the **Aleph** compilation process to get a better idea of what is going on. Some system might require all libraries. More compiler flags can be used, and should be used.

### 2.3.3 Testing the result

With the library ready to use, it is possible to run an **Aleph** session and see what is happening.

```
zsh> aleph
aleph> interp:library "example-api"
aleph> println (add 1 2)
3
aleph> C-d
zsh >
```

This is it. If it does not work, you should check the `LD_LIBRARY_PATH` environment variable. In last resort, the directory `exp/api` contains a `Makefile` designed to work correctly, but it won't install the library.

---

# CHAPTER 3

## Object Class

---

The **Object** class is the *pillar* of the **Aleph** engine. The class defines the base methods that are used during the *eval-apply* process. The class provides also the methods to control the object locking as well as the object reference count.

### 3.1 Object evaluation

The simplest object evaluation is the one that takes an object and returns an object. Most of the time this evaluation is *reflexive*. That is the calling object is returned. In this case, the object is said to be *self evaluated*.

#### 3.1.1 Object eval-apply methods

The **Object** class contains several overloaded **eval** and **apply** methods. The simplest one requires only a *runnable* and *nameset* objects.

```
class Object {
    ... many declarations

    /// evaluate an object in the current nameset
    /// @param robj    the current runnable
    /// @param nset    the current nameset
    virtual Object* eval (class Runnable* robj, class Nameset* nset);

    /// apply an object with a set of arguments
    /// @param robj    the current runnable
    /// @param nset    the current nameset
    /// @param args    the arguments to apply
    virtual Object* apply (class Runnable* robj, class Nameset* nset,
                          class Cons* args);
}
```

#### 3.1.2 Eval default implementation

The default implementation for the **eval** method is to return the calling object (aka *this*). As mentioned earlier, such behavior is called *self evaluation*. Most of the objects evaluates to themselves. This include all literal objects such like *Integer* or *String*.

```

    // evaluate an object in the current nameset
    Object* Object::eval (Runnable* robj, Nameset* nset) {
        return this;
    }
}

```

It is remarkable to notice how such simple implementation can be so powerful.

### 3.1.3 Qualified name evaluation

The evaluation of a qualified name is a repetitive process that goes for each lexical element of that name. For example, the qualified name `hello:world` is evaluated first by evaluating `hello` which in turn evaluates `world`. Since, the evaluation by name is too costly in terms of string comparison, the qualified name evaluation is done by a `quark` mechanism.

### 3.1.4 Quark definition

A quark is unique integer representation for a given string. The term `quark` comes from the *Window System* which has a similar mechanism. For a given string, a quark is constructed with the static string method `intern`.

```
static const long QUARK_TOSTRING = String::intern ("to-string");
```

When a qualified name is constructed by the lexical analyzer, an equivalent quark representation is computed automatically. This process makes now the qualified name evaluation a straight-forward recursive system that involves just integer comparison.

## 3.2 Static construction

In order for the interpreter to construct a new object, the class has to provide a static method that returns such object based on an argument vector.

```

/// generate a new boolean
/// @param argv the argument vector
static Object* mknew (Vector* argv);

```

The vector argument contains *evaluated object*. It is up to the implementation to call the appropriate constructor, depending on the arguments type and values.

### 3.2.1 Argument vector interface

The `Vector` class provides several method that ease the transformation between object and native types.

- `length`  
returns the number of elements in this vector
- `getInt`  
returns a native integer by index
- `getbool`  
returns a native boolean by index

- `getreal`  
returns a native real (double) by index
- `getchar`  
returns a native character by index
- `getstring`  
returns a string object by index

As an example, we reproduce here the implementation of the **BitSet** class.

```
Object* BitSet::mknew (Vector* argv) {
    long argc = (argv == nilp) ? 0 : argv->length ();
    if (argc == 0) return new BitSet;
    if (argc == 1) {
        long size = argv->getint (0);
        return new BitSet (size);
    }
    throw Exception ("argument-error", "too many argument for bitset");
}
```

This implementation provides two ways to create a **bitSet** object. Without argument, the argument vector length is null and the method return a new object by calling the default constructor. With one argument, a new bit set is created with a specific size. The other cases throw an exception. Note that an exception can be raised by the `getint` method if the object argument cannot be mapped to an integer value.

Another way to access the argument object is by performing directly *dynamic casting*. We left the code fragment below of the **Character** class as an exercise.

```
Object* Character::mknew (Vector* argv) {
    if ((argv == nilp) || (argv->length () == 0)) return new Character;
    if (argv->length () != 1)
        throw Exception ("argument-error",
            "too many argument with character constructor");
    // try to map the character argument
    Object* obj = argv->get (0);
    if (obj == nilp) return new Character;

    // try an integer object
    Integer* ival = dynamic_cast <Integer*> (obj);
    if (ival != nilp) return new Character (ival->tointeger ());

    // try a character object
    Character* cval = dynamic_cast <Character*> (obj);
    if (cval != nilp) return new Character (*cval);

    // try a string object
    String* sval = dynamic_cast <String*> (obj);
    if (sval != nilp) return new Character (*sval);

    // illegal object
    throw Exception ("type-error", "illegal object with character"
        obj->repr ());
}
```

### 3.3 A simple object

Writing a new C++ object that is usable by the **Aleph** engine is quite simple. The following example implements the behavior of a *boolean*. The class is called `Boolean` and is available in the standard library. We implement here a simple version without qualified name support, but this minimal example will compile and can be constructed in the interpreter.

```
#ifndef EXAMPLE_BOOLEAN_HPP
#define EXAMPLE_BOOLEAN_HPP

#ifndef ALEPH_OBJECT_HPP
#include "Object.hpp"
#endif

namespace example {
    // use the aleph namespace
    using namespace aleph;

    /// The example::Boolean class
    class Boolean : public Object {
    private:
        /// the native boolean
        bool d_value;

    public:
        /// create a new default boolean
        Boolean (void);

        /// create a boolean by value
        Boolean (const bool value);

        /// @return the class name
        String repr (void) const;

        /// create a new boolean
        static Object* mknew (Vector* argv);
    }
}
#endif
```

This is the minimal declaration that is needed to compile the boolean example. Note that the default constructor is not really needed, but it is given here for illustration purpose.

#### 3.3.1 The default constructor

The default constructor is not really needed here, but it is generally wise to provide a default implementation. Remember that a default constructor is one of the six default implementation provided by the compiler for a given class. It is a good practice to have basic things under control.

```
namespace example {
    // create a default boolean
    Boolean::Boolean (void) {
        d_value = false;
    }
}
```

```

// create a boolean by value
Boolean::Boolean (const bool value) {
    d_value = value;
}
}

```

### 3.3.2 The representation method

The **repr** method is one of the mandatory method for an object derivation since it is defined as *virtual pure* in the `Object` base class. The method returns a string representation of that class, that is here the string "Boolean".

```

namespace example {
    // return the class name
    String Boolean::repr (void) const {
        return "Boolean";
    }
}

```

### 3.3.3 The static constructor

The implementation for the static constructor is trivial. We accept only 0 or one argument and create a new boolean object.

```

namespace example {
    // create a boolean in a generic way
    static Object* Boolean::mknew (Vector* argv) {
        long argc = (argv == nilp) ? 0 : argv->length ();
        if (argc == 0) return new Boolean;
        if (argc == 1) {
            long value = argv->getbool (0);
            return new Boolean (value);
        }
        throw Exception ("argument-error", "too many argument for boolean");
    }
}

```

### 3.3.4 First compilation

If we assume that the standard **Aleph** headers are located under the `/usr/local/include/aleph/std`, we can compile the previous example, assuming we are using `gcc`.

```

zsh > gcc -D_REENTRANT -I. -I/usr/local/include/aleph/std
        -I/usr/local/include/aleph/std -o Boolean.o -c Boolean.cpp

```

The flags for compiling in debug mode, all warnings, no standard include files, etc. can be used as well. We will see in the next chapter how to use the standard **Aleph** makefile to develop a complete library. If you plan to use your own build system, a complete list of directives and recommendation is given in the next chapter as well. If you plan to contribute to the **Aleph** distribution, there are more constraints attached to the build process which are described in a specific *Contributing to Aleph* chapter.
