# Agenda

- ▶ How do you attack the DNS?
- ▶ What has been discovered?
- ▶ Short term solutions
- ▶ Long term solutions
- ▶ Work ICANN has done to help

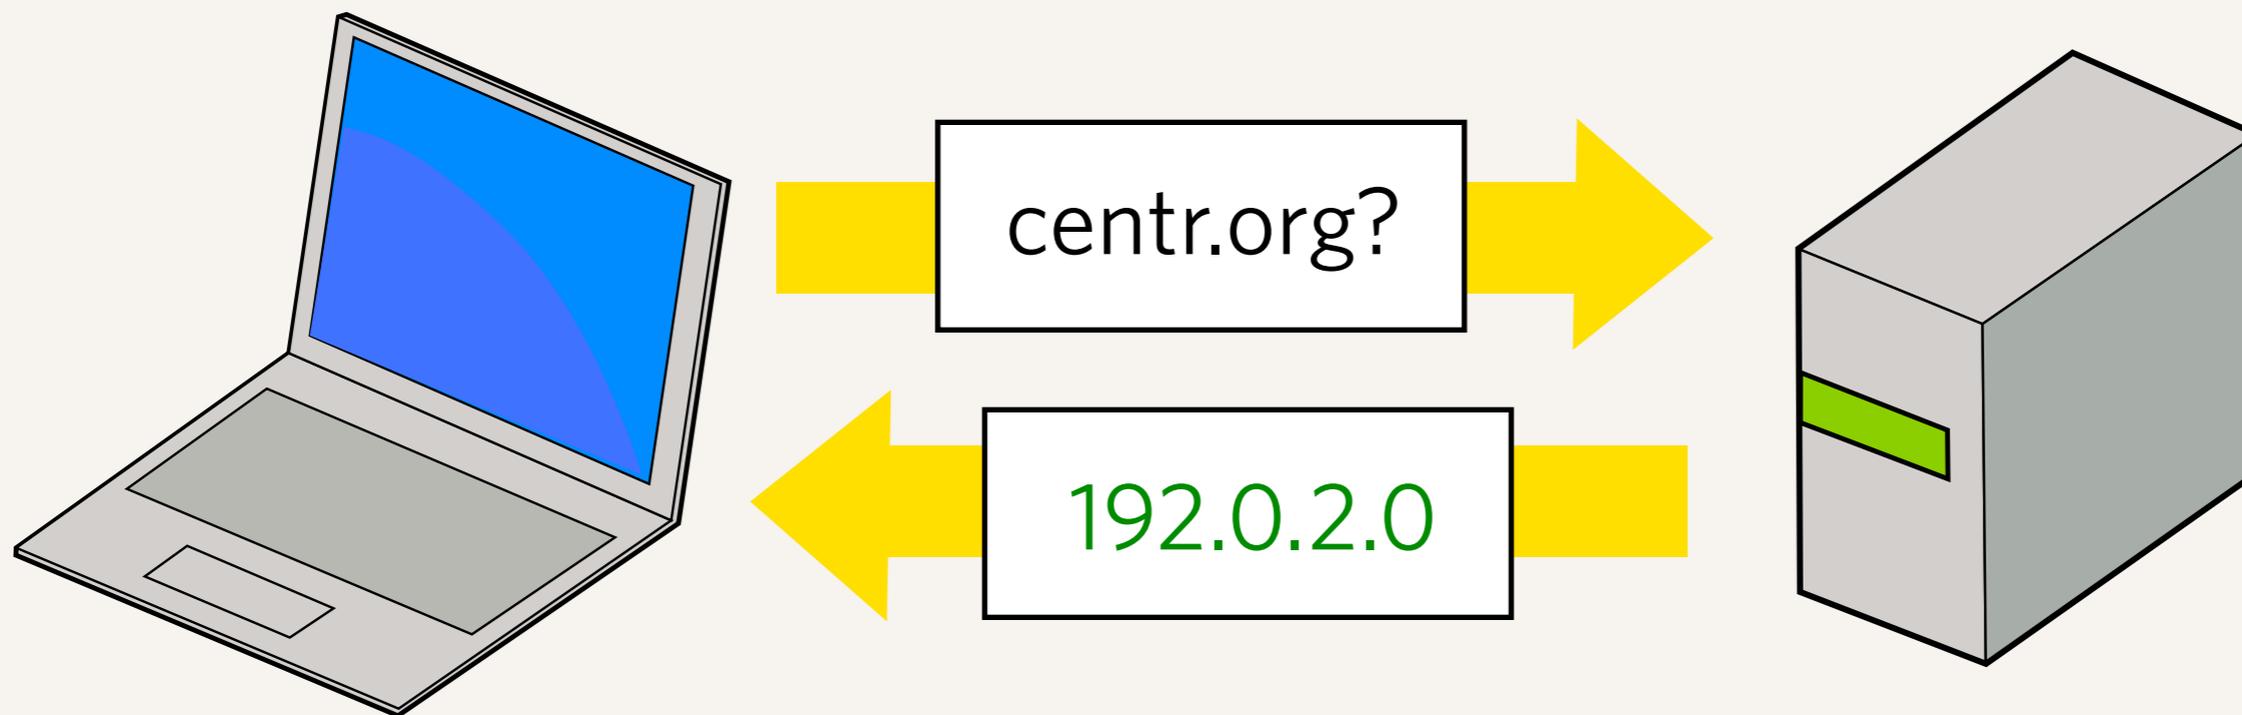

**How do you attack the DNS?**

A typical DNS query

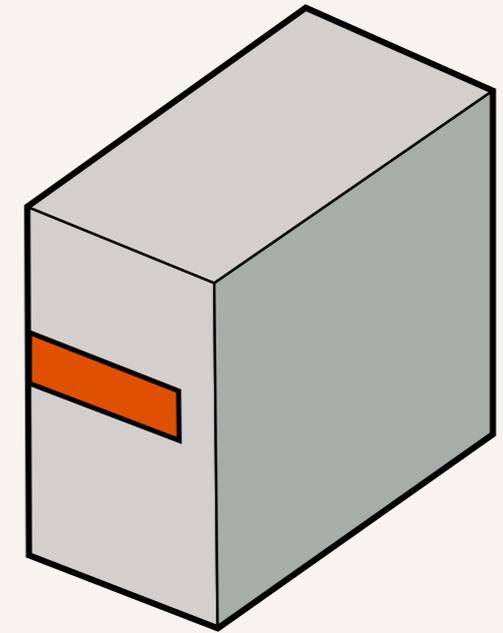

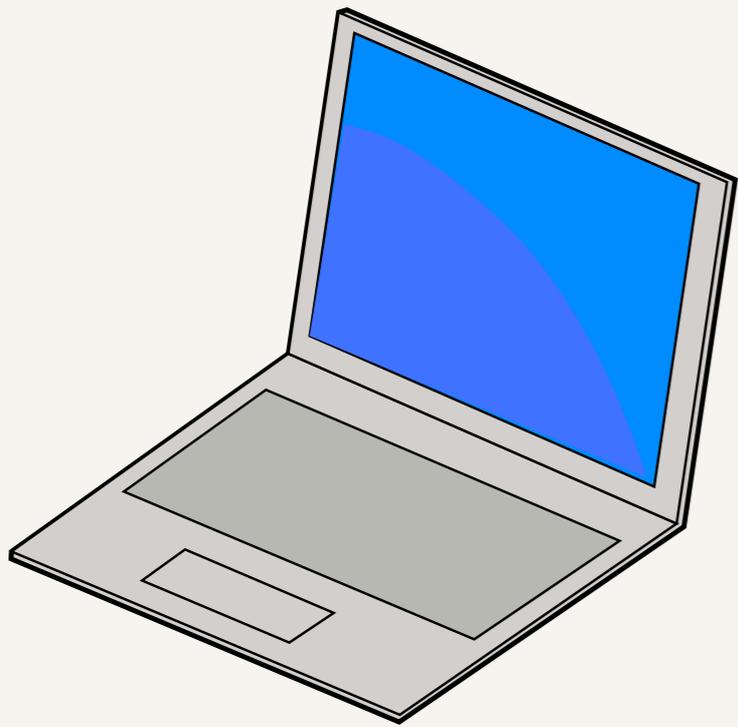

A typical DNS query

A typical DNS query

# The DNS is not secure

- ▶ A computer sends a “question” to a DNS server, asking a question like “What is the IP address for aftld.org?”
- ▶ The computer gets an answer, and if the answer appears to match the question it asked, completely trusts that it is correct.
- ▶ There are multiple ways that traffic on the Internet can be intercepted and rerouted, or impersonated, so that the answer given is false.

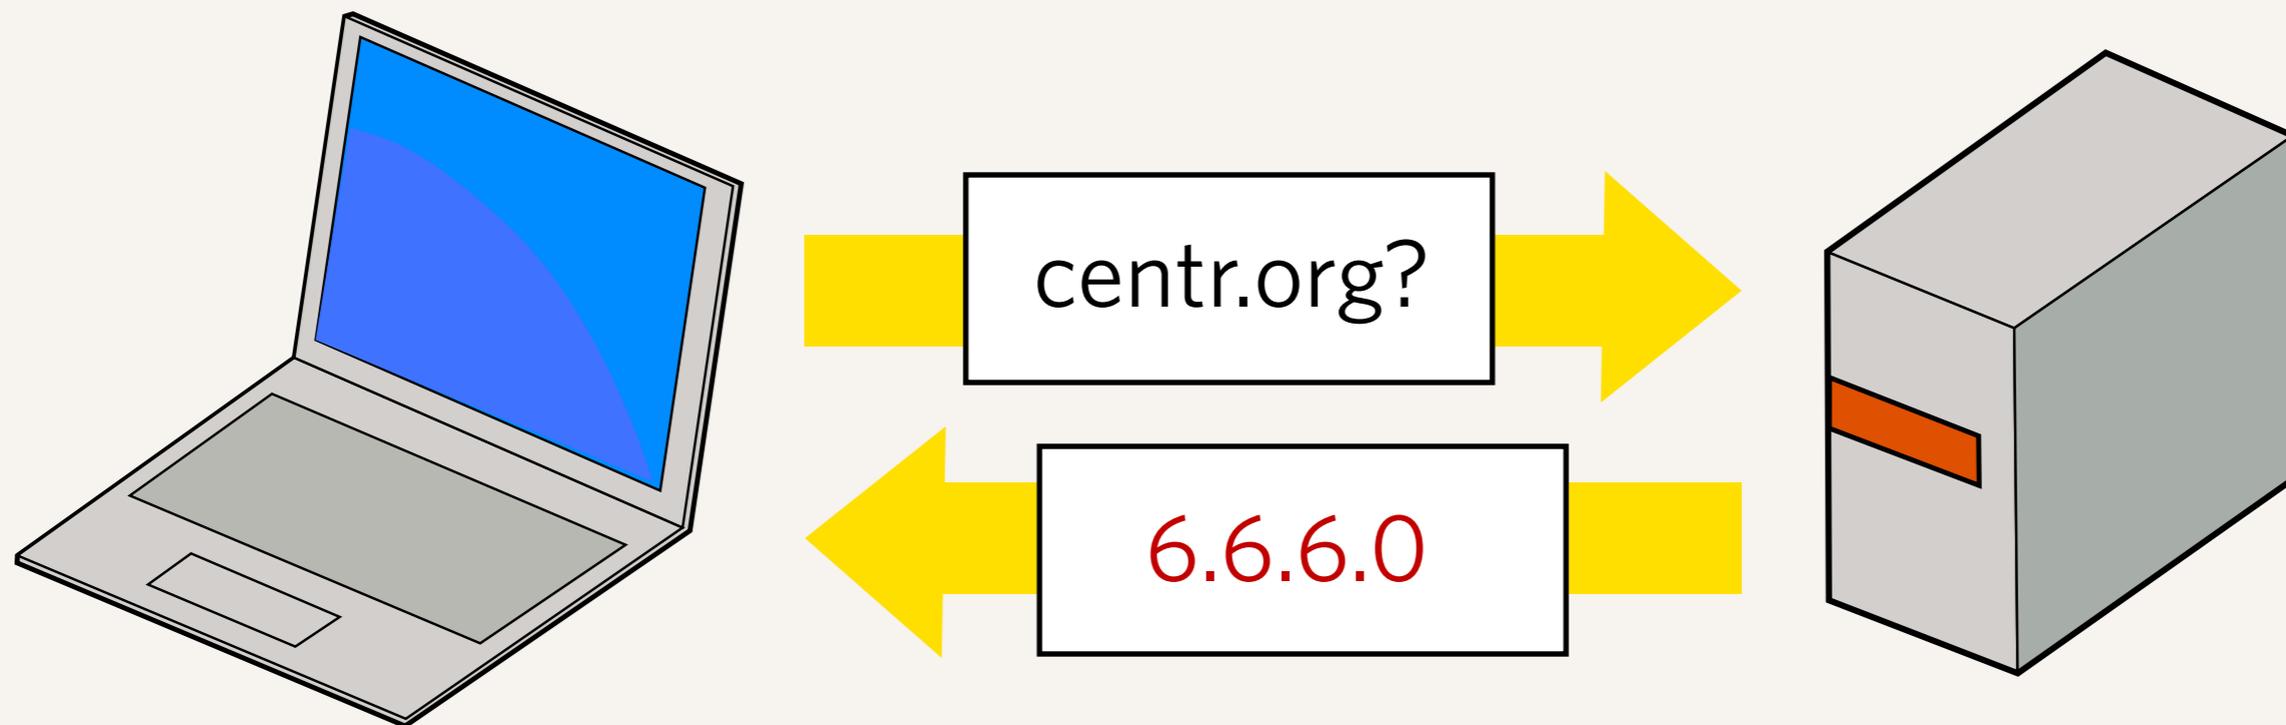

## Receiving the wrong answer

- ▶ Something in the network between the computer and the server has intercepted or redirected the traffic.

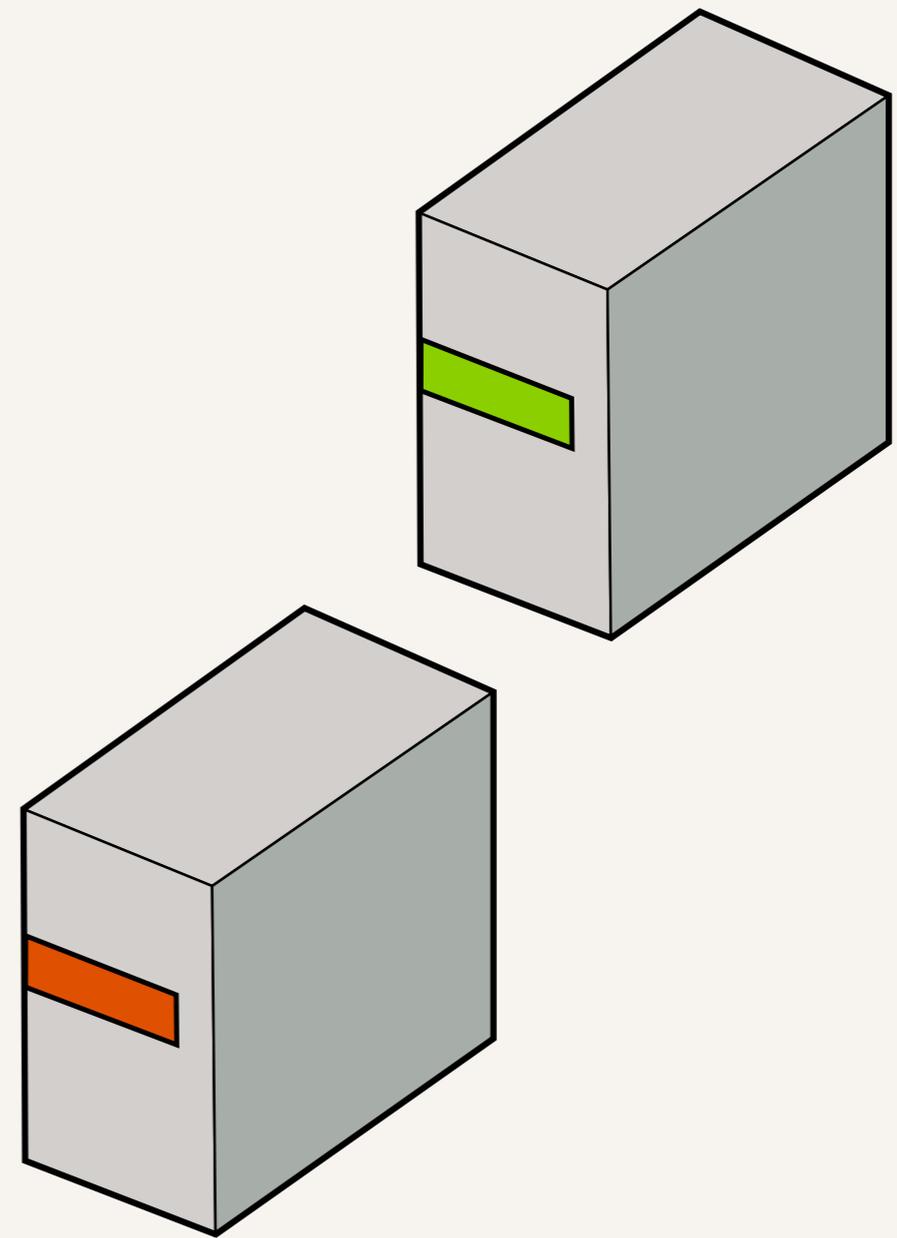

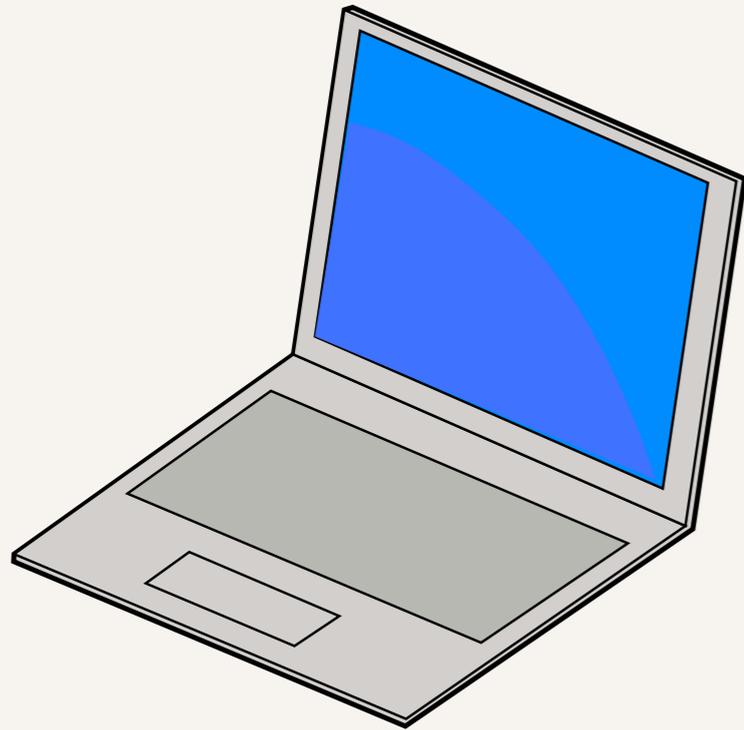

## Receiving the wrong answer

- ▶ Something in the network between the computer and the server has intercepted or redirected the traffic.

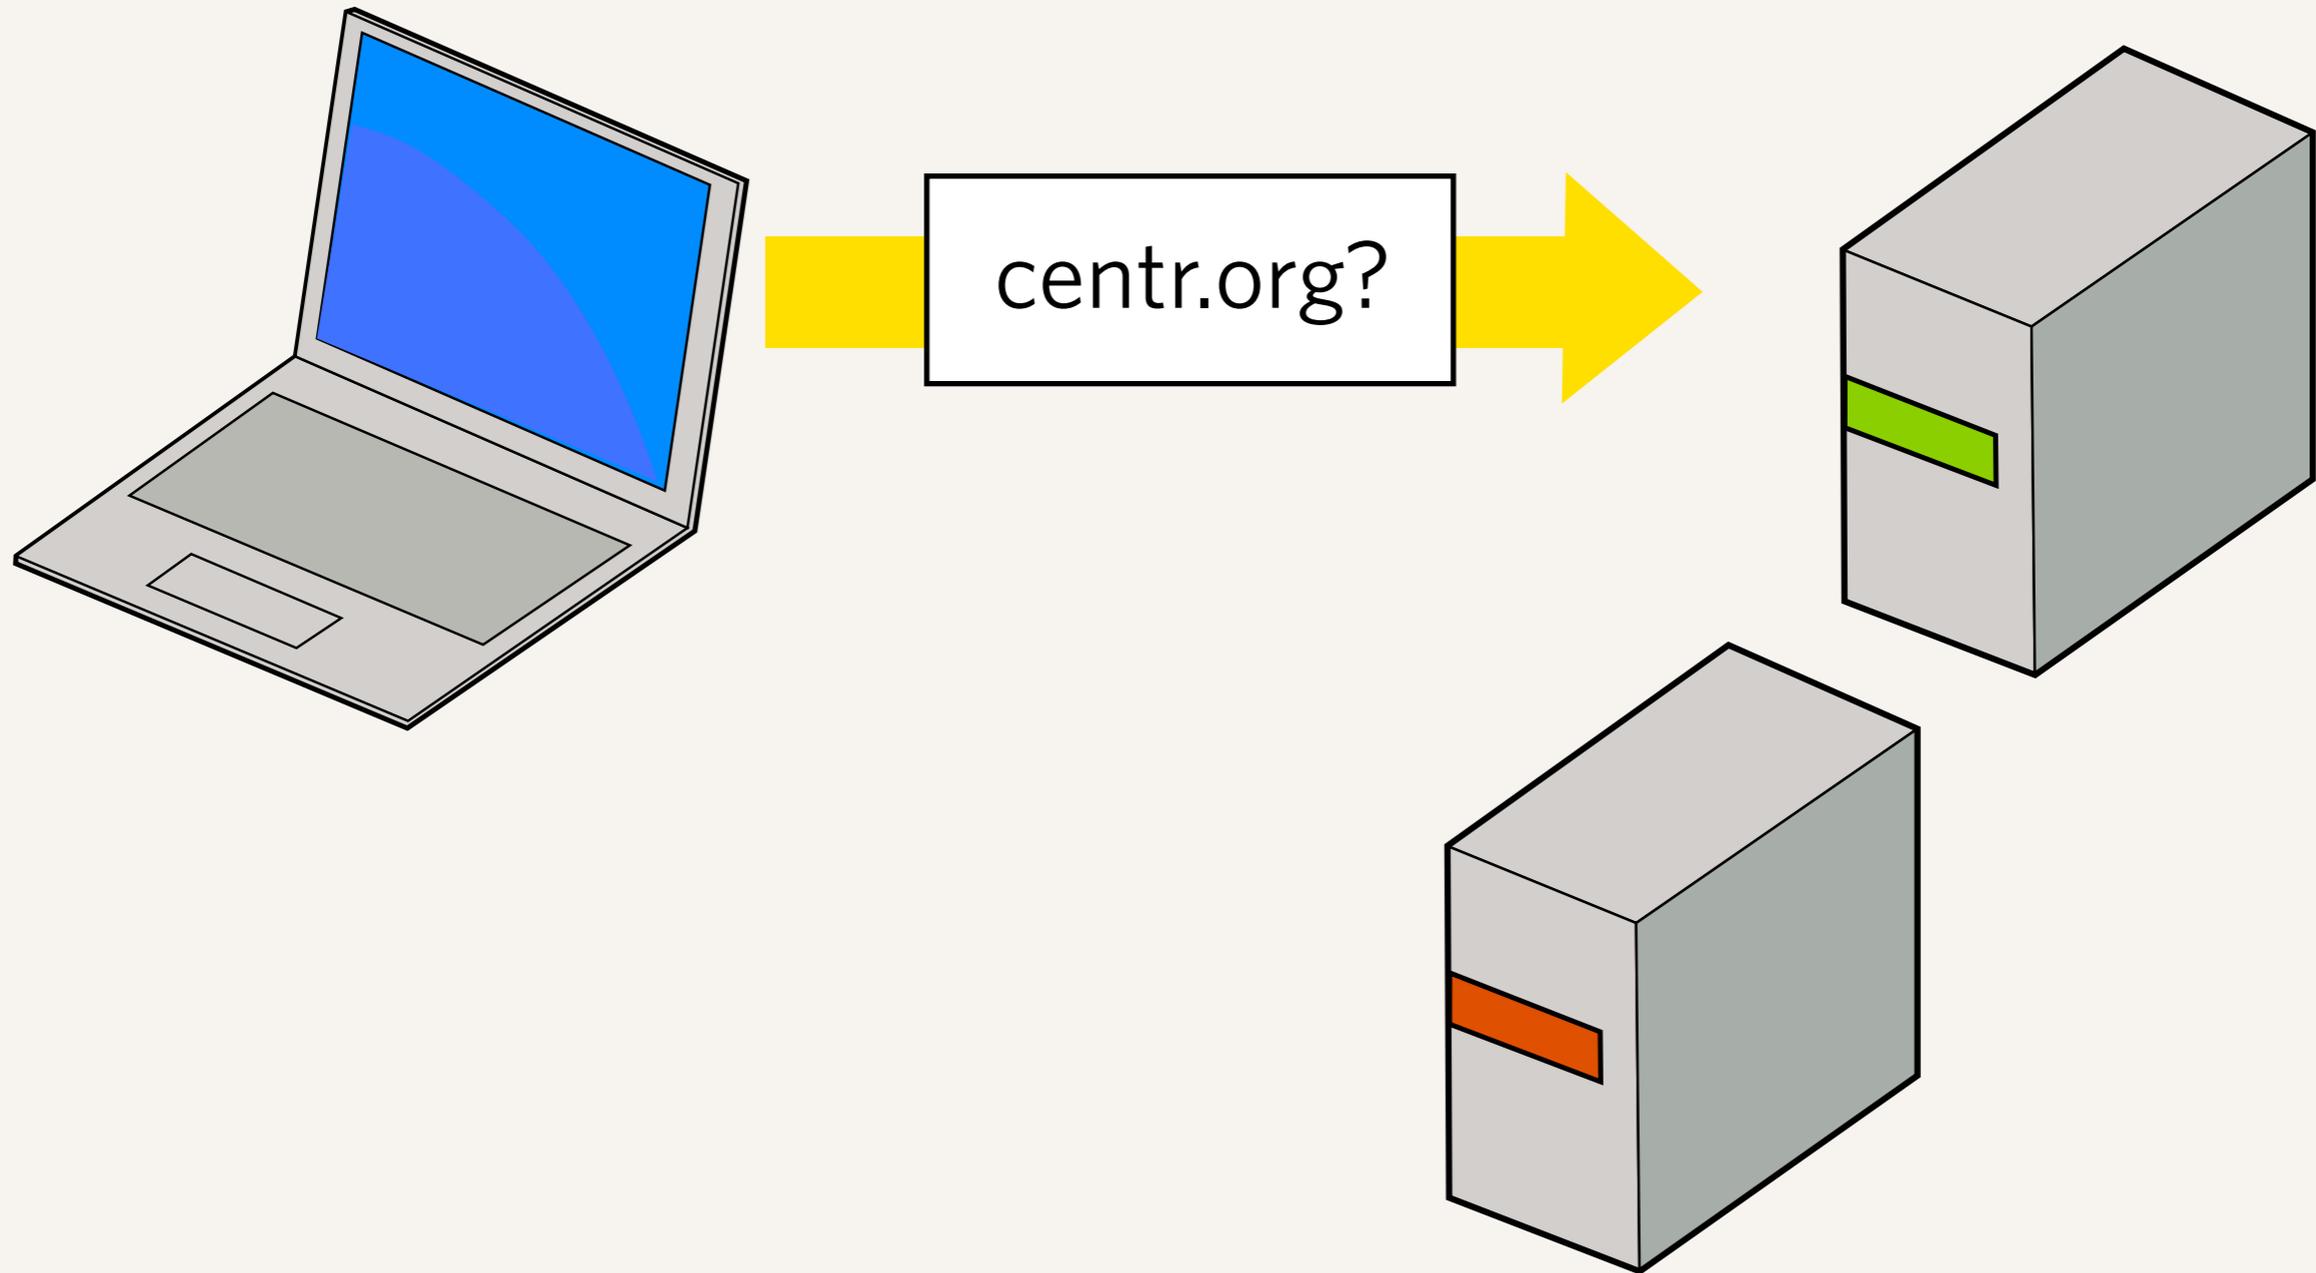

## Receiving the wrong answer

- ▶ Something in the network between the computer and the server has intercepted or redirected the traffic.

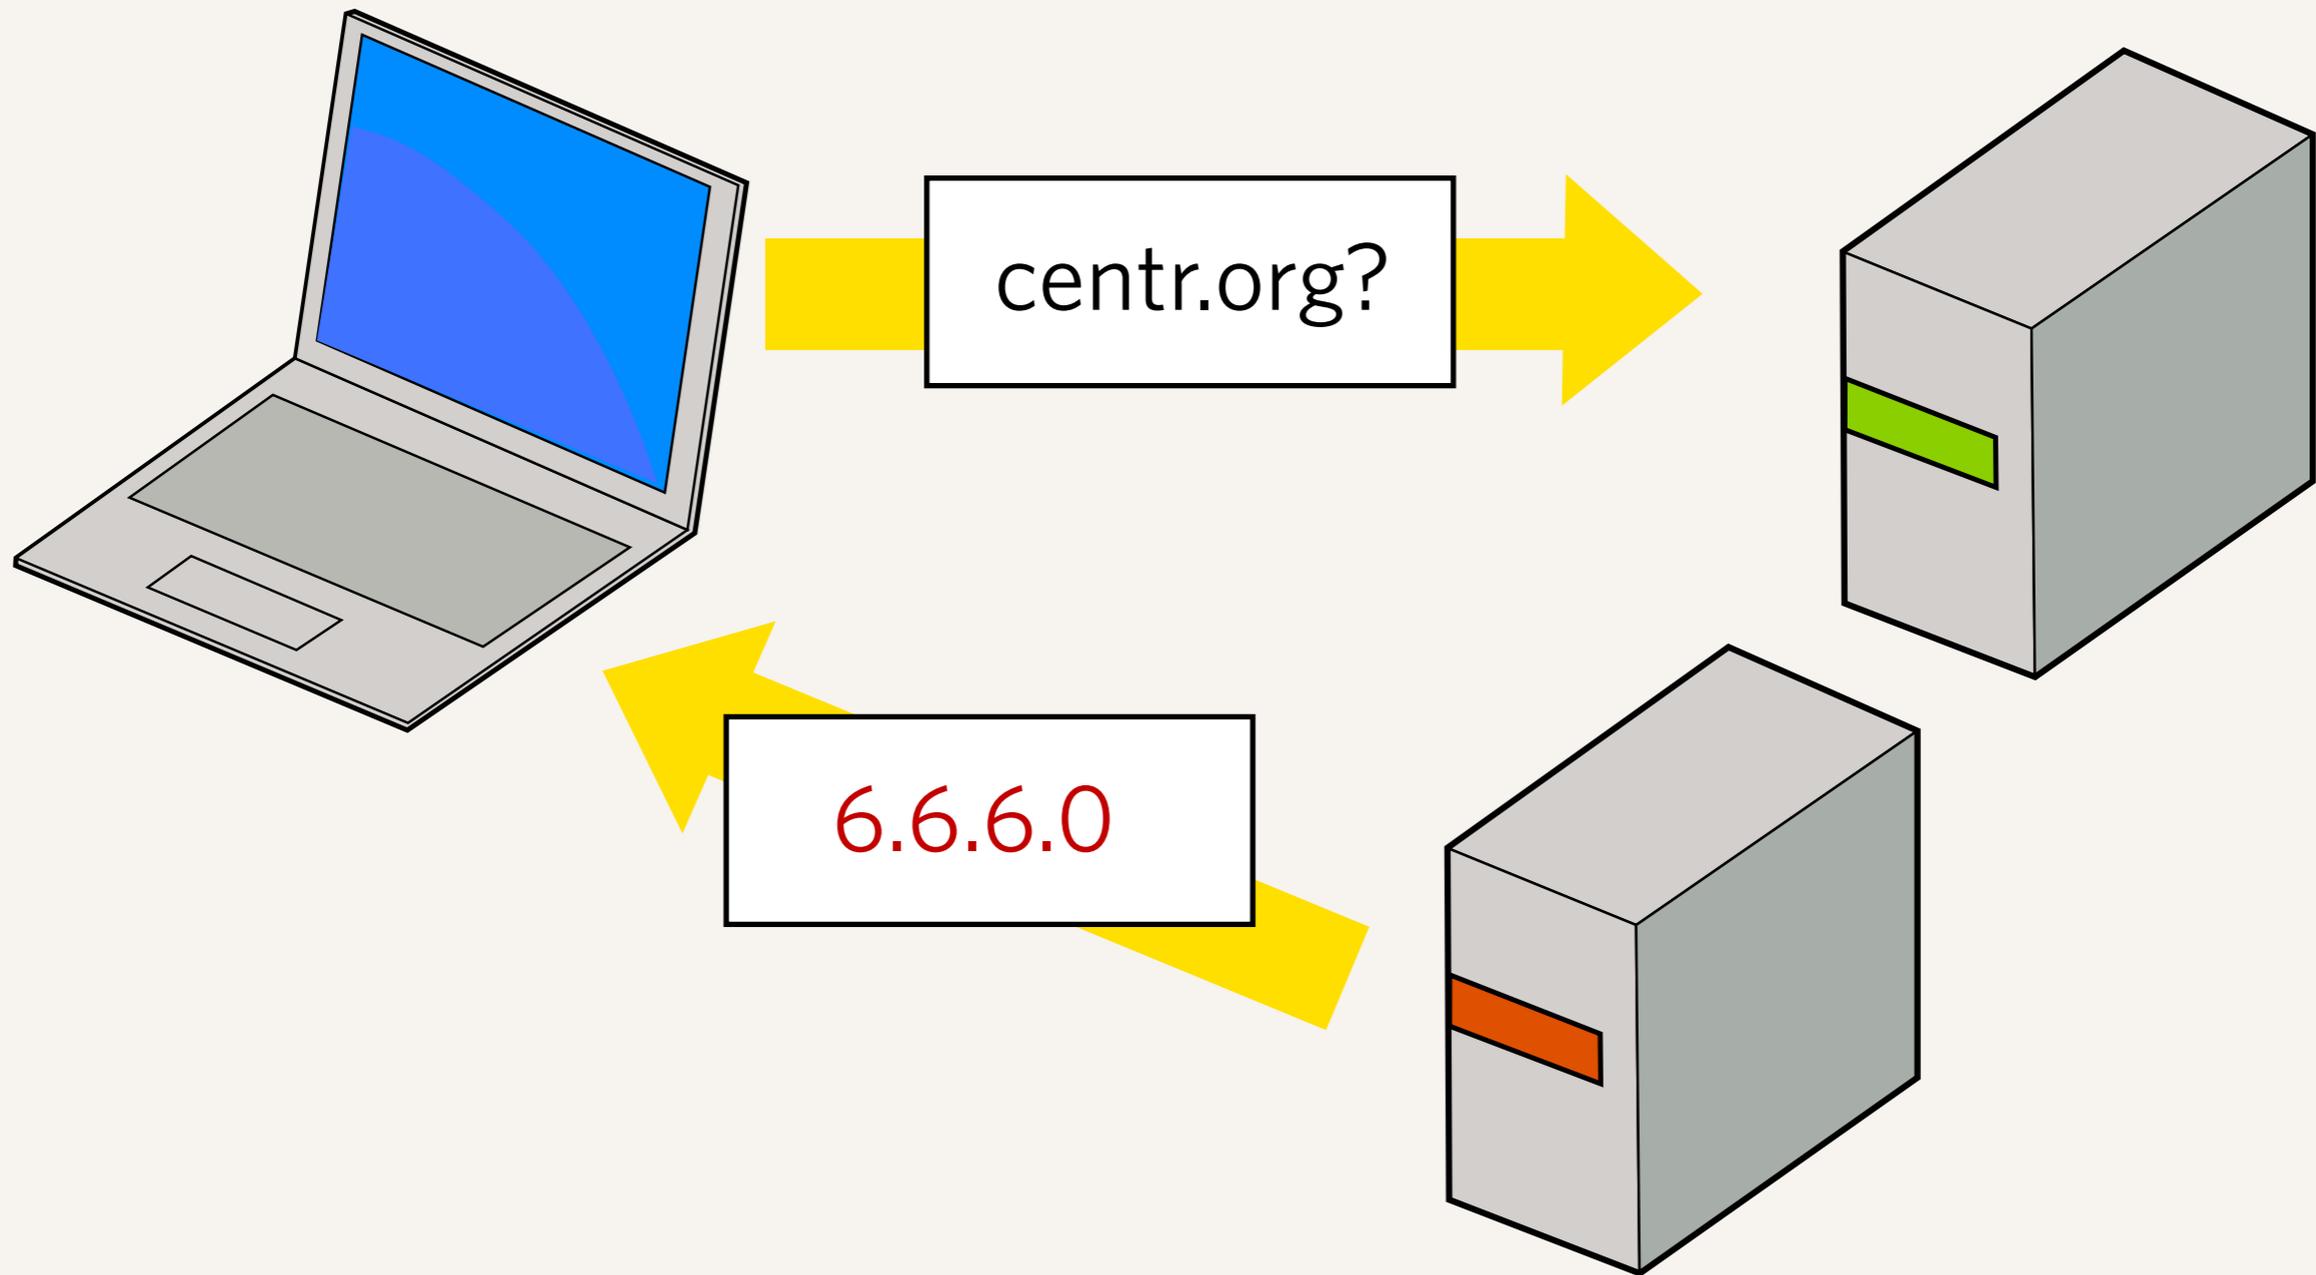

## Receiving the wrong answer

- ▶ A server on the network responds with the wrong answer, quicker than the correct server can give the right answer.

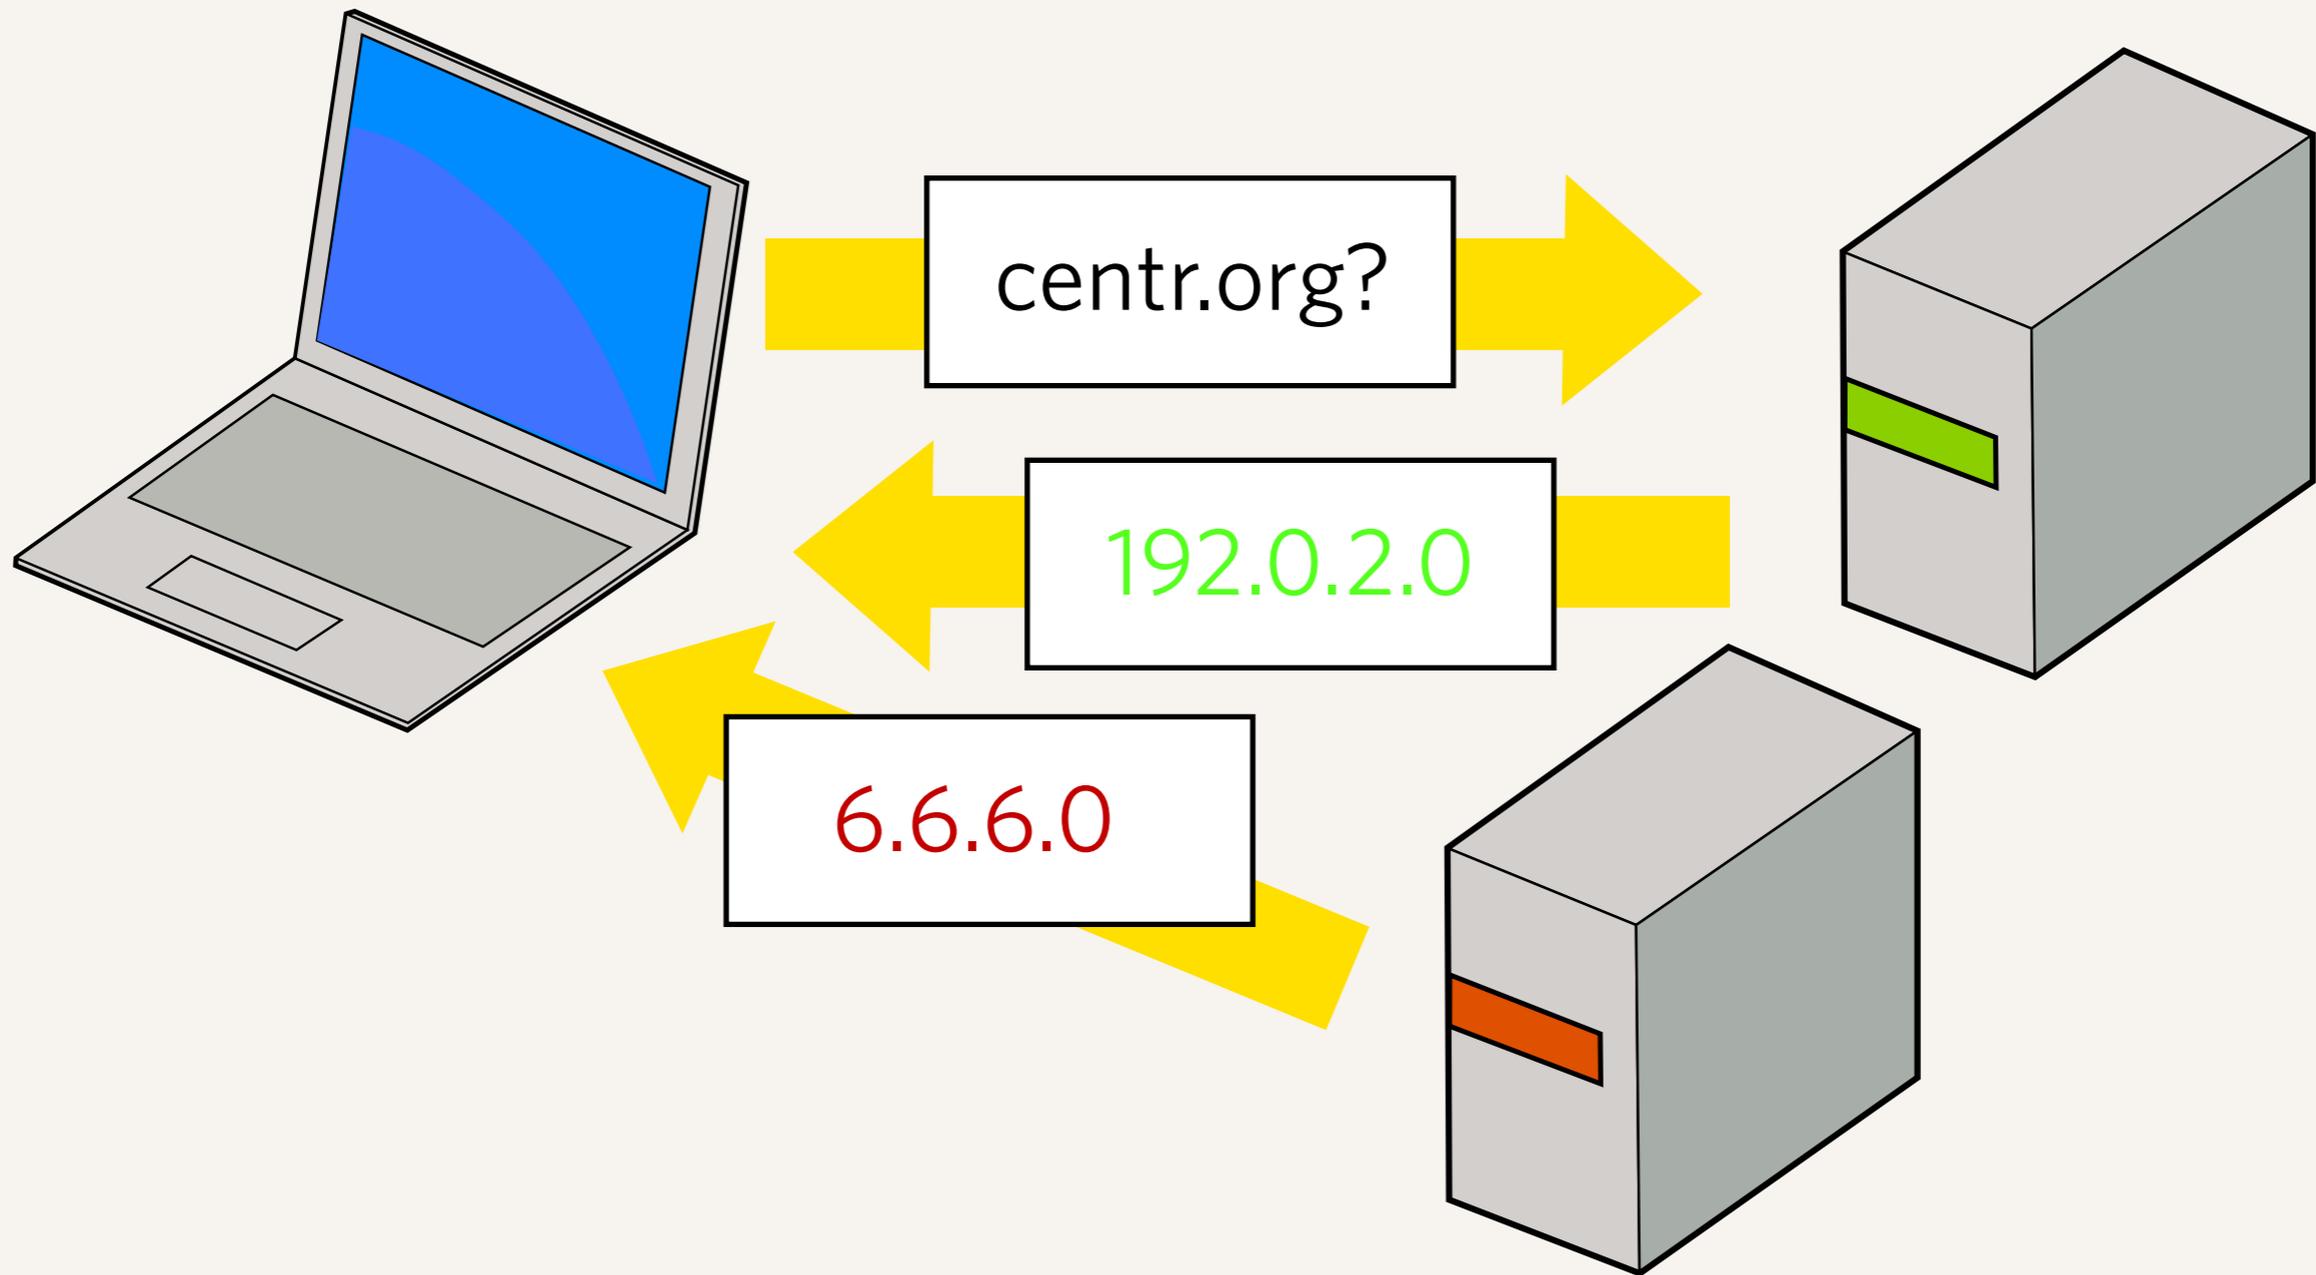

## Receiving the wrong answer

- ▶ A server on the network responds with the wrong answer, quicker than the correct server can give the right answer.

## Receiving the wrong answer

- ▶ A server on the network responds with the wrong answer, quicker than the correct server can give the right answer.

## Receiving the wrong answer

- ▶ A server on the network responds with the wrong answer, quicker than the correct server can give the right answer.

# Cache poisoning

- ▶ To improve efficiency, DNS servers typically store results in a cache to speed further lookups.
  - ▶ This is the typical configuration at ISPs, etc.
- ▶ If the wrong answer gets remembered it will be served to future lookups.
  - ▶ One successful cache poisoning attack can therefore affect many users.

# How does one spoof a response

- ▶ A question is sent out, and the querying computer waits for an answer to return
- ▶ It knows it has received the answer to its question when several attributes in the answer match the question it asked
  - ▶ It comes back to the same IP address it was sent from
  - ▶ It comes back to the same port number it was sent from
  - ▶ The question matches the question asked
  - ▶ A unique transaction number matches what was sent

# To spoof a response

- ▶ You need to get all these attributes the same in your forged answer packet
  - ▶ The IP address needs to match. If you know the IP address of the recursive name server this is known by the attacker, and does not need to be guessed.
  - ▶ The question needs to match. The attacker will know what this is, because they will be injecting their own questions into the recursive server.
  - ▶ What remains to guess is the transaction number and the port number

*But...*

# But...

- ▶ Everything I have told you so far has been known for years.

**What has been discovered recently?**

# This attack is highly effective

- ▶ Dan Kaminsky identified there is a straightforward way to flood the recursive server with lots of answers, so that the right combination would be sent very quickly (a few seconds)
- ▶ It was also identified that the two identifiers the attacker needs to guess are not fully random (or not random at all)

# Why is this attack concerning to TLDs?

- ▶ If a name server provides both recursive and authoritative name service, a successful attack on the recursive portion can store bad data that is given to computers that want authoritative answers.
- ▶ The net result is one could insert or modify domain data inside a TLD.

# Short term solutions

# 1. Maximise the amount of randomness

- ▶ Most implementations use randomised transaction numbers already. (The risk with that was discovered years ago, and fixed in most software)
- ▶ Most implementations do NOT randomise the port number. In fact most always used the same port number (53, the port number IANA has assigned for DNS)
- ▶ The patches that have been released in the last few months work by randomising the source port for the recursive server.

## 2. Disable open recursive name servers

- ▶ The attack is not effective if the attacker can not send question packets to the name server.
- ▶ If you must run a recursive name server, limit access to only those computers that need it. (e.g. your customers). The will still be able to execute the attack, but the exposure is constrained.
- ▶ Turning off open recursive name servers is a good idea anyway, because they can be used for other types of attack (denial of service)

**Long term solution**

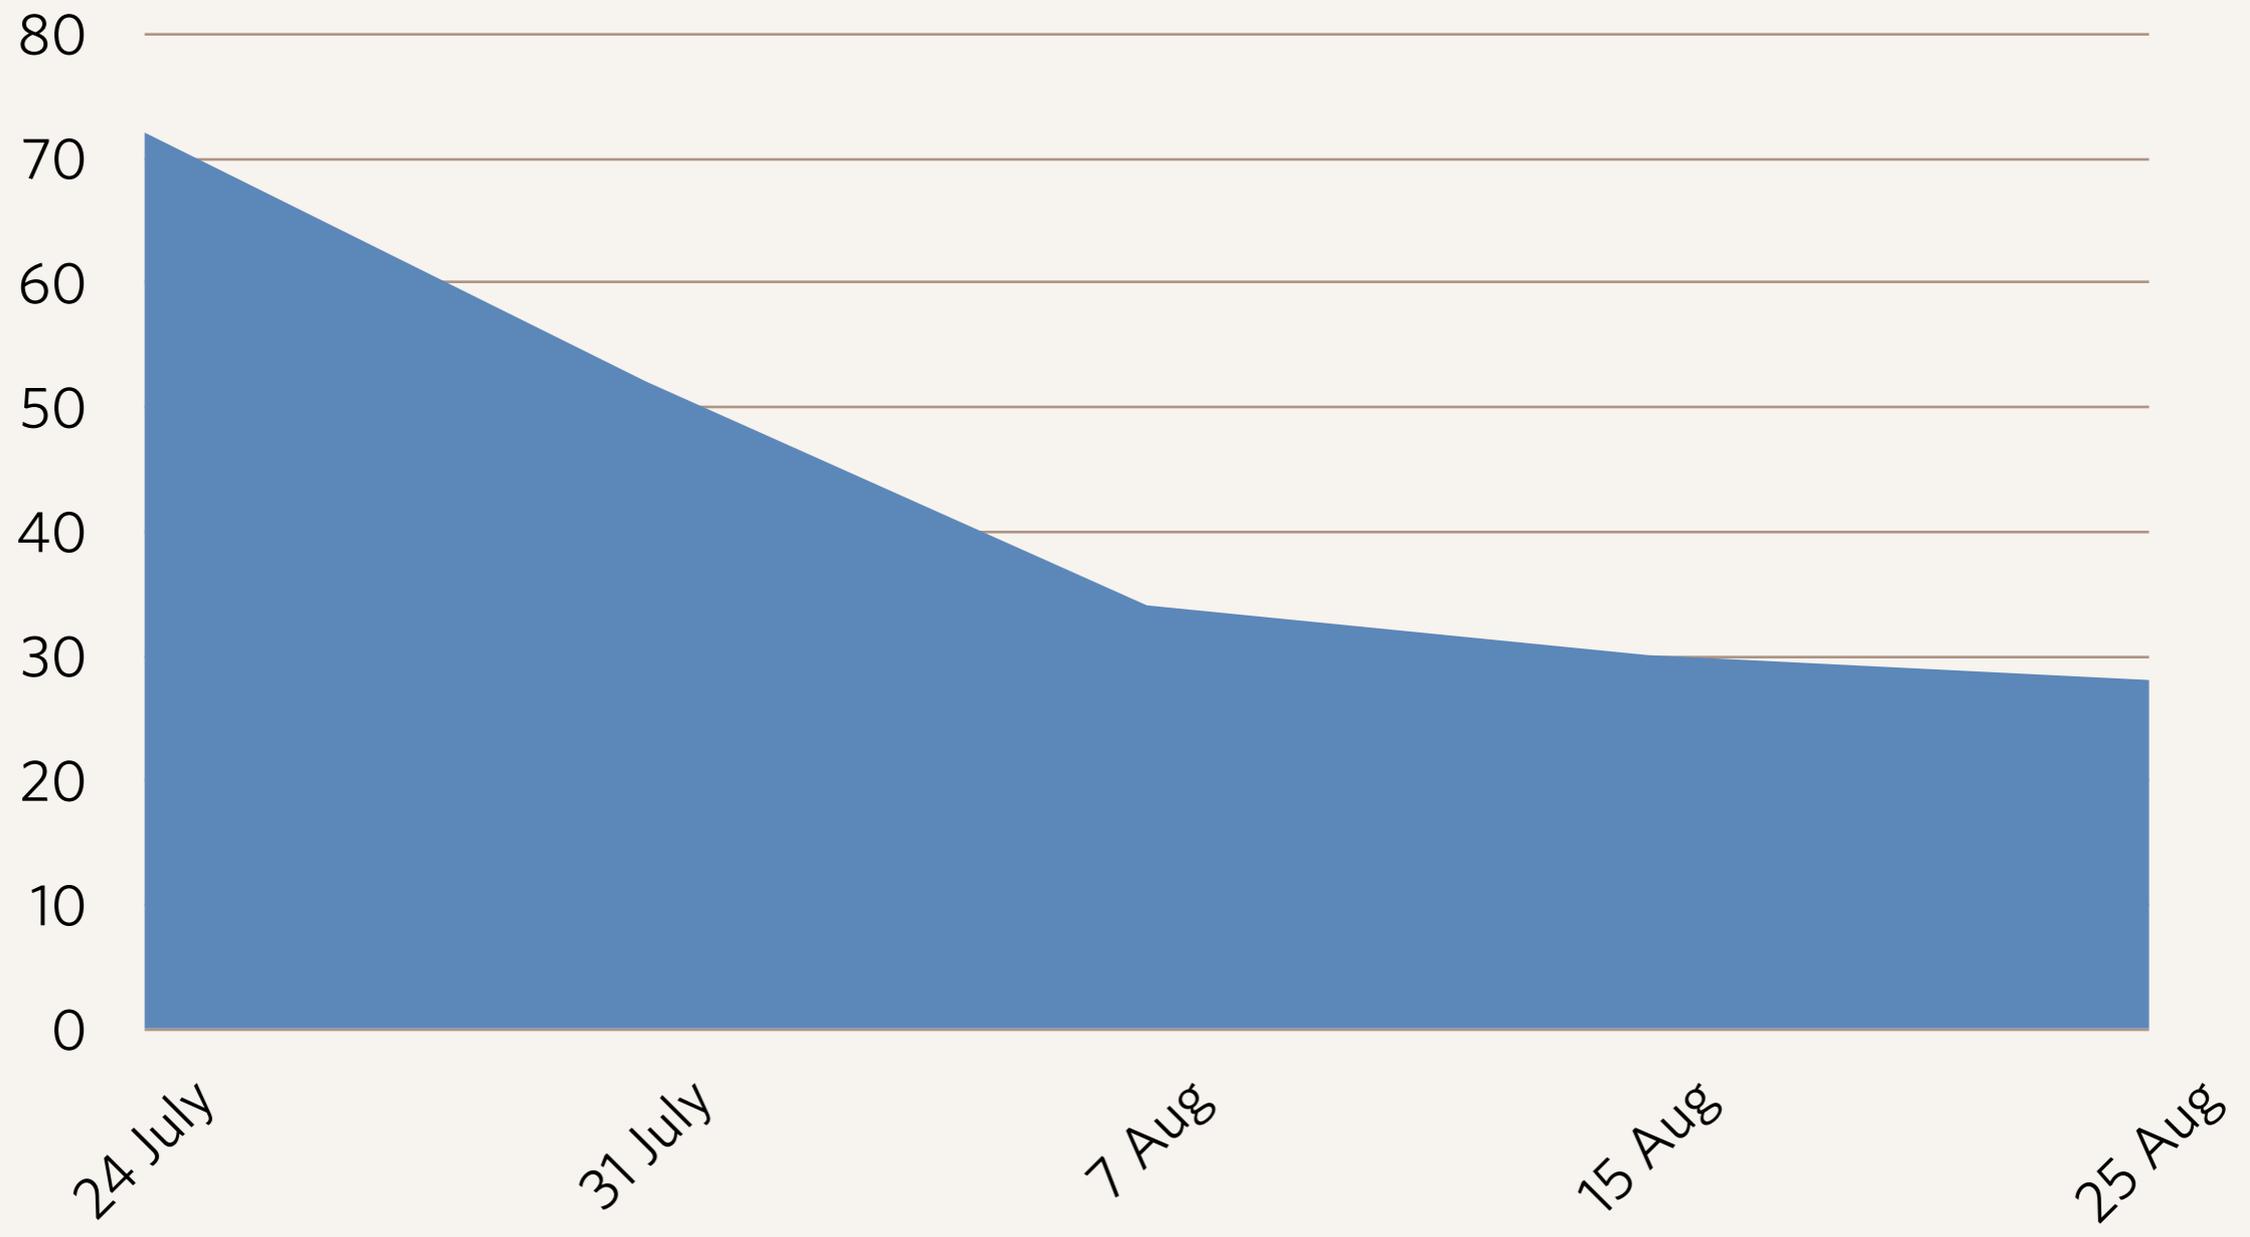

# Introduce security to the DNS

- ▶ The DNS is insecure. Upgrade the DNS for security.
- ▶ DNSSEC is the current answer to this problem.
- ▶ This attack provides clear incentive to deploy a solution like DNSSEC, because without security the DNS will continue to be vulnerable to cache poisoning attacks.

**What has ICANN done**

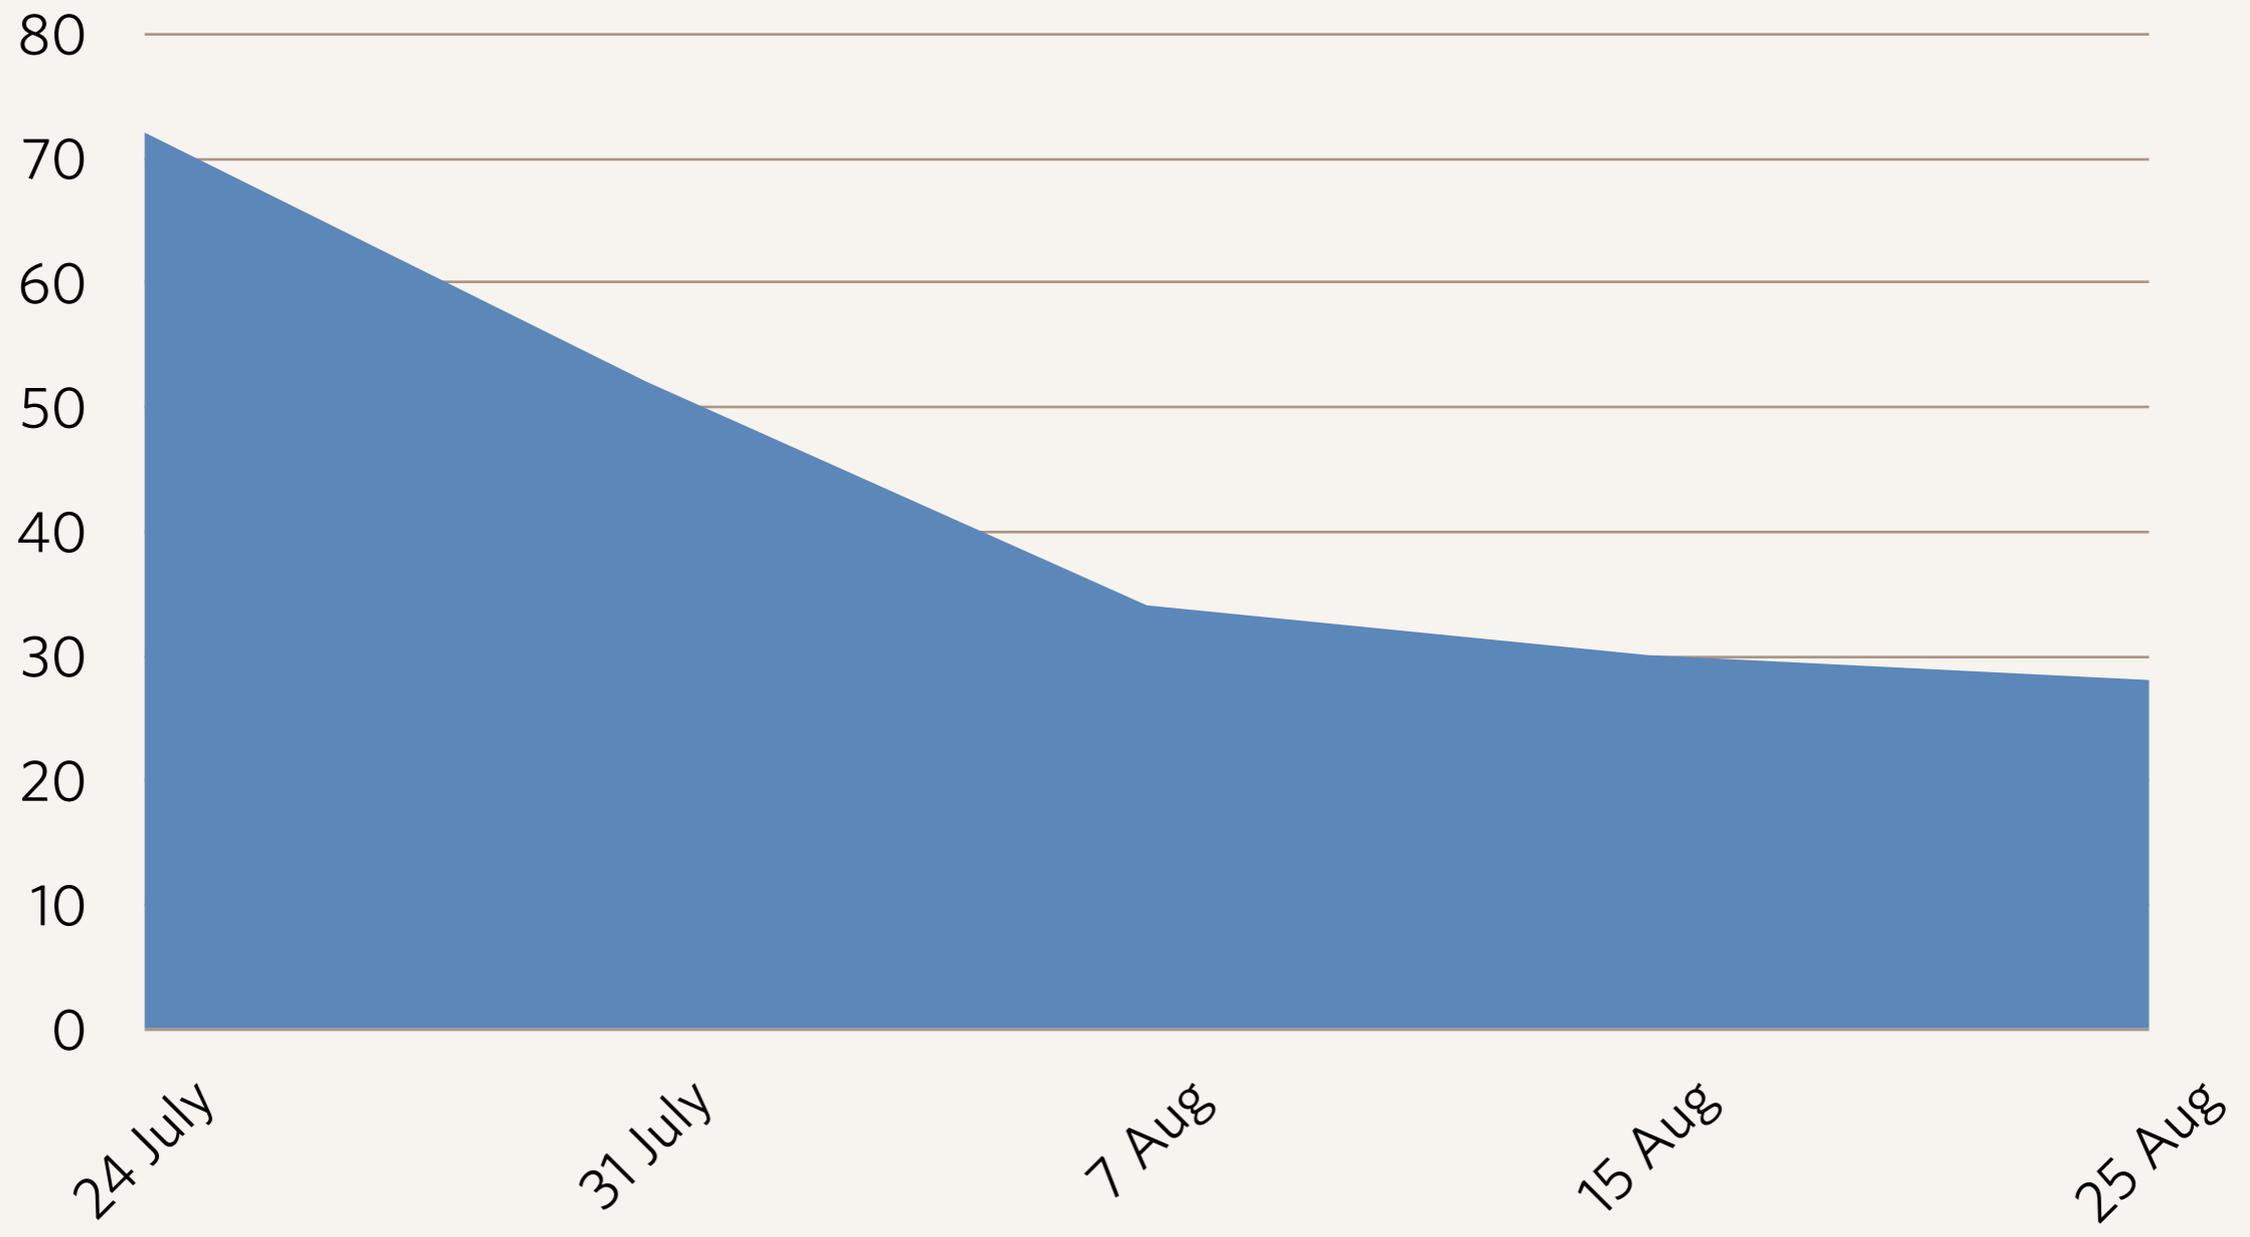

# Impact on TLDs

- ▶ At the time the vulnerability became known, a survey of TLD operators found that 72 TLDs had authorities that were providing open recursive service.
- ▶ ICANN contacted all TLDs affected
  - ▶ Explained the situation, and the urgency to fix it
  - ▶ Provided advice on how to reconfigure name servers
  - ▶ Expedited root zone change requests, if required

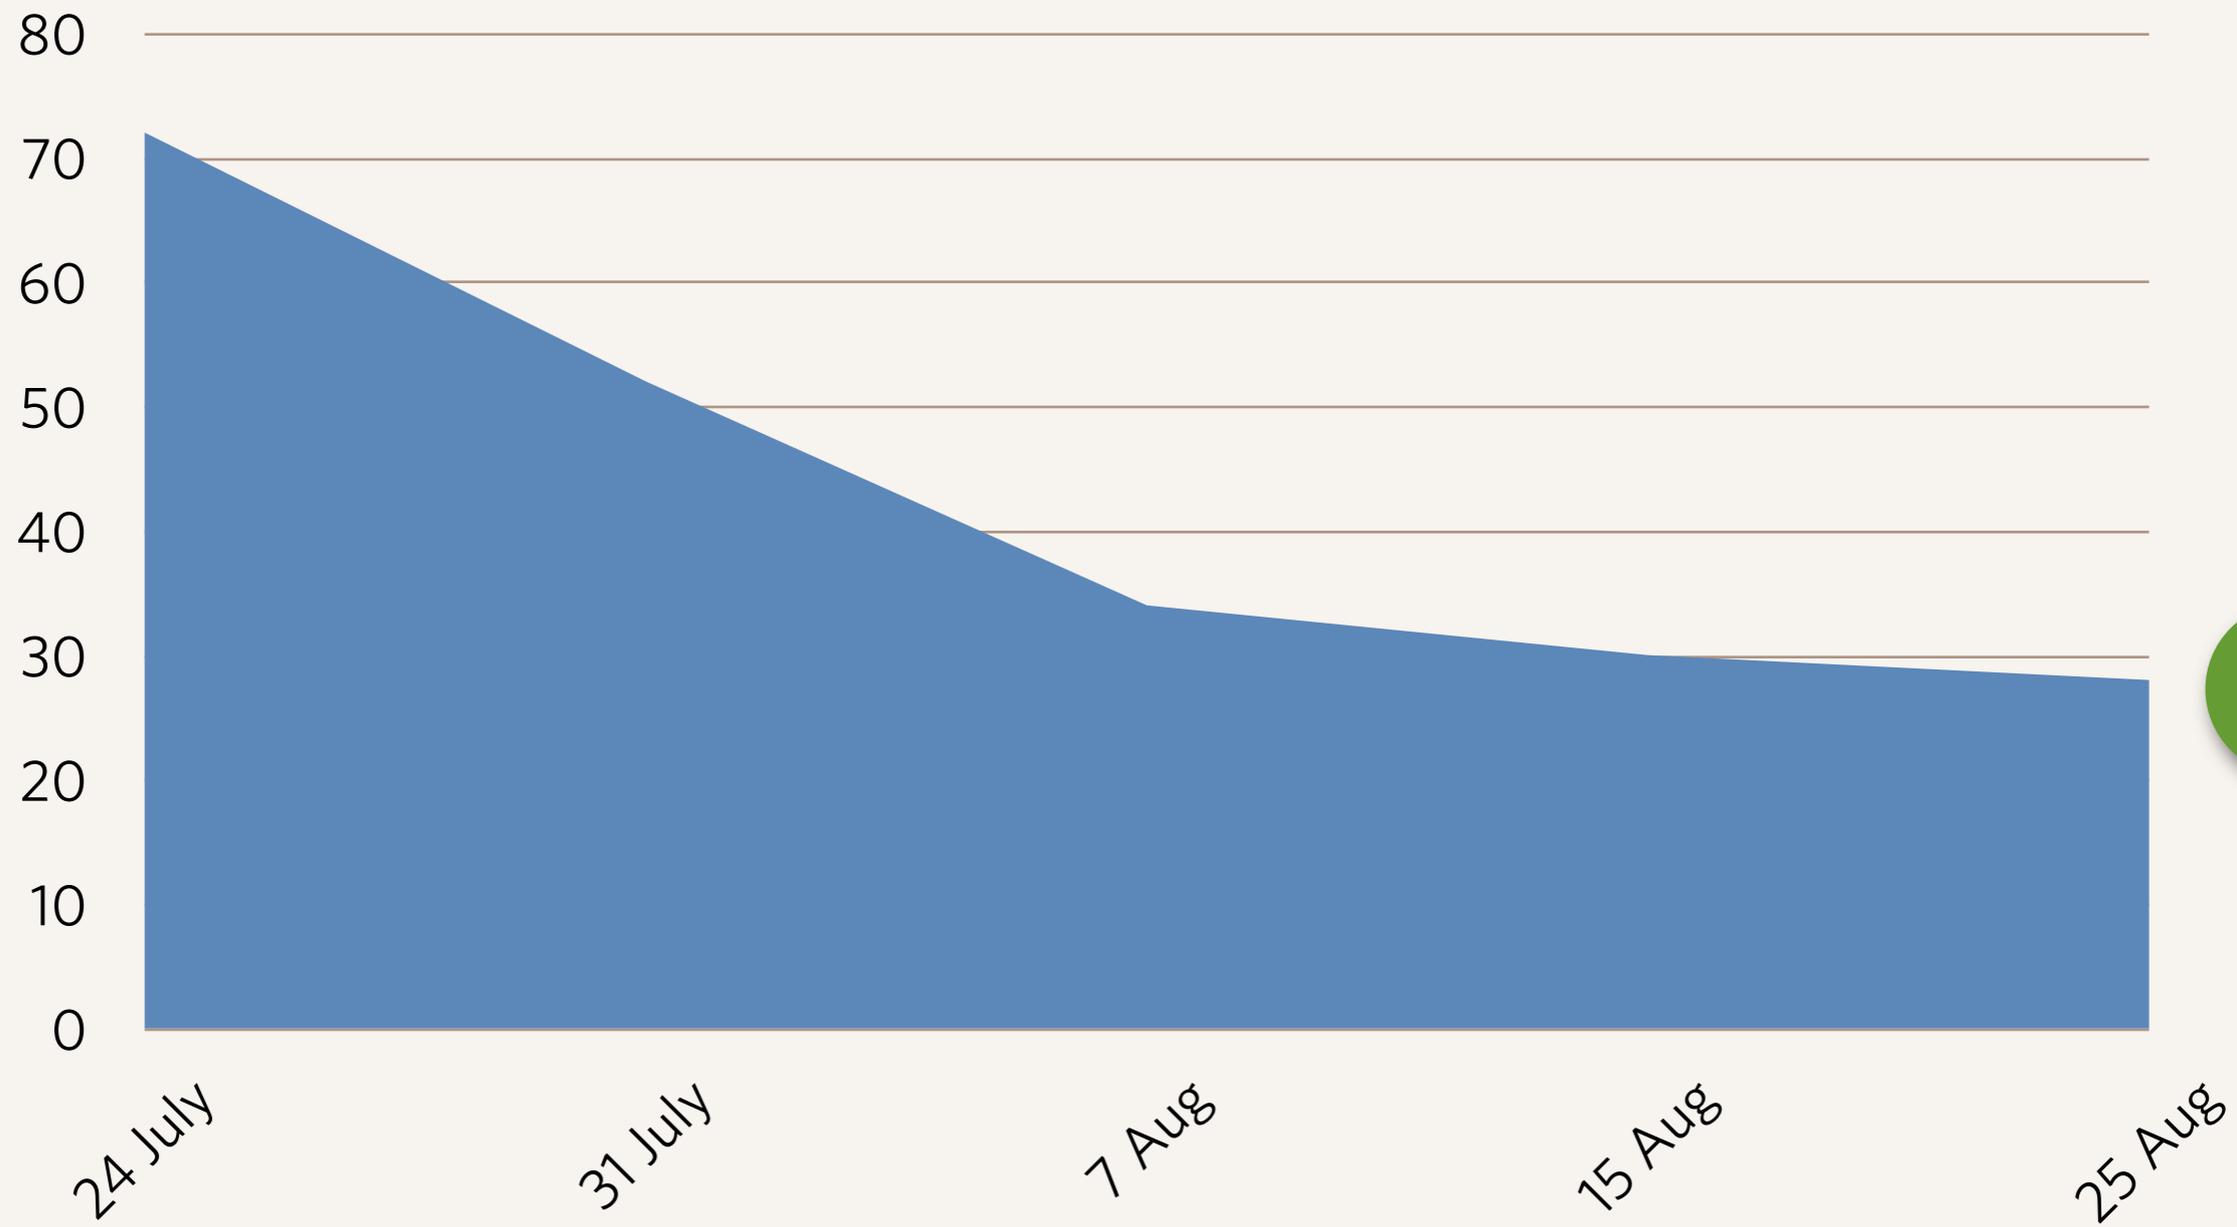

TLDs affected

72

TLDs affected

72

26

TLDs affected

# Checking tool

- ▶ We developed a tool which we ran daily against TLDs, and shared results with affected TLDs.
- ▶ It became clear a web-based tool where TLD operators could self-test would be useful, so it was reimplemented this way.
- ▶ The tool is not TLD specific, and works with any domain name.
- ▶ It is at <http://recursive.iana.org/>

IANA — Cross-Pollination Scan

http://recursive.iana.org/ Google

## Cross-Pollination Check

The discovery of a [highly-effective cache poisoning attack](#) that can affect name servers providing recursive name service has made it important that such servers be patched to mitigate against the problem. Furthermore, the risk of cache poisoning for servers that share recursive and authoritative functions can cross-pollinate the authoritative function with incorrect data. This tool is designed to assess the authorities for a given domain and determine whether they provide vulnerable recursive service.

Provide a **domain name** to analyse

**Safe.**  
The servers tested for CENTR.ORG appear to not be vulnerable to cache poisoning.

Name server	IP Address	Results
NS1.OPENMINDS.BE	195.47.215.14	Not recursive
NS2.OPENMINDS.BE	195.47.215.13	Not recursive
NS3.OM-POWERED.NET	85.12.30.141	Not recursive

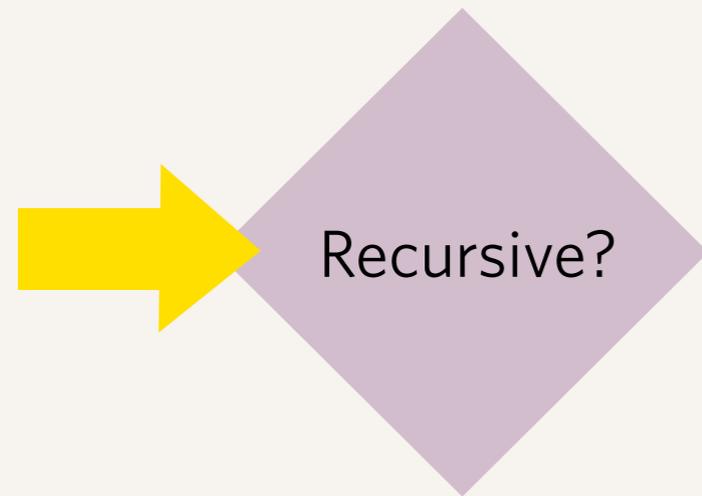

### Notes about this tool

This tool has been implemented quickly to assist name server operators. It may have problems as it has not been thoroughly tested, so you should also perform your own tests and use this only as a guide. We appreciate any comments or bug reports on this tool — please drop a note to [iana@iana.org](mailto:iana@iana.org). Port entropy results provided by [DNS-OARC](#).

# Vulnerability checking tool

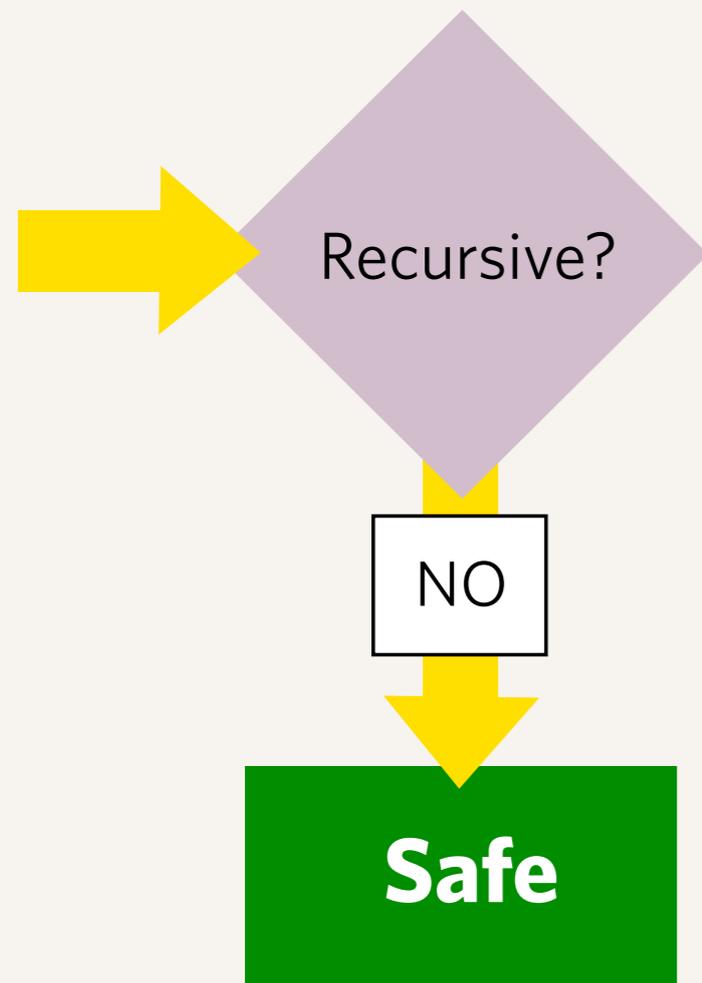

# How the tool works

- ▶ The tool checks for the two aspects that enable the attack

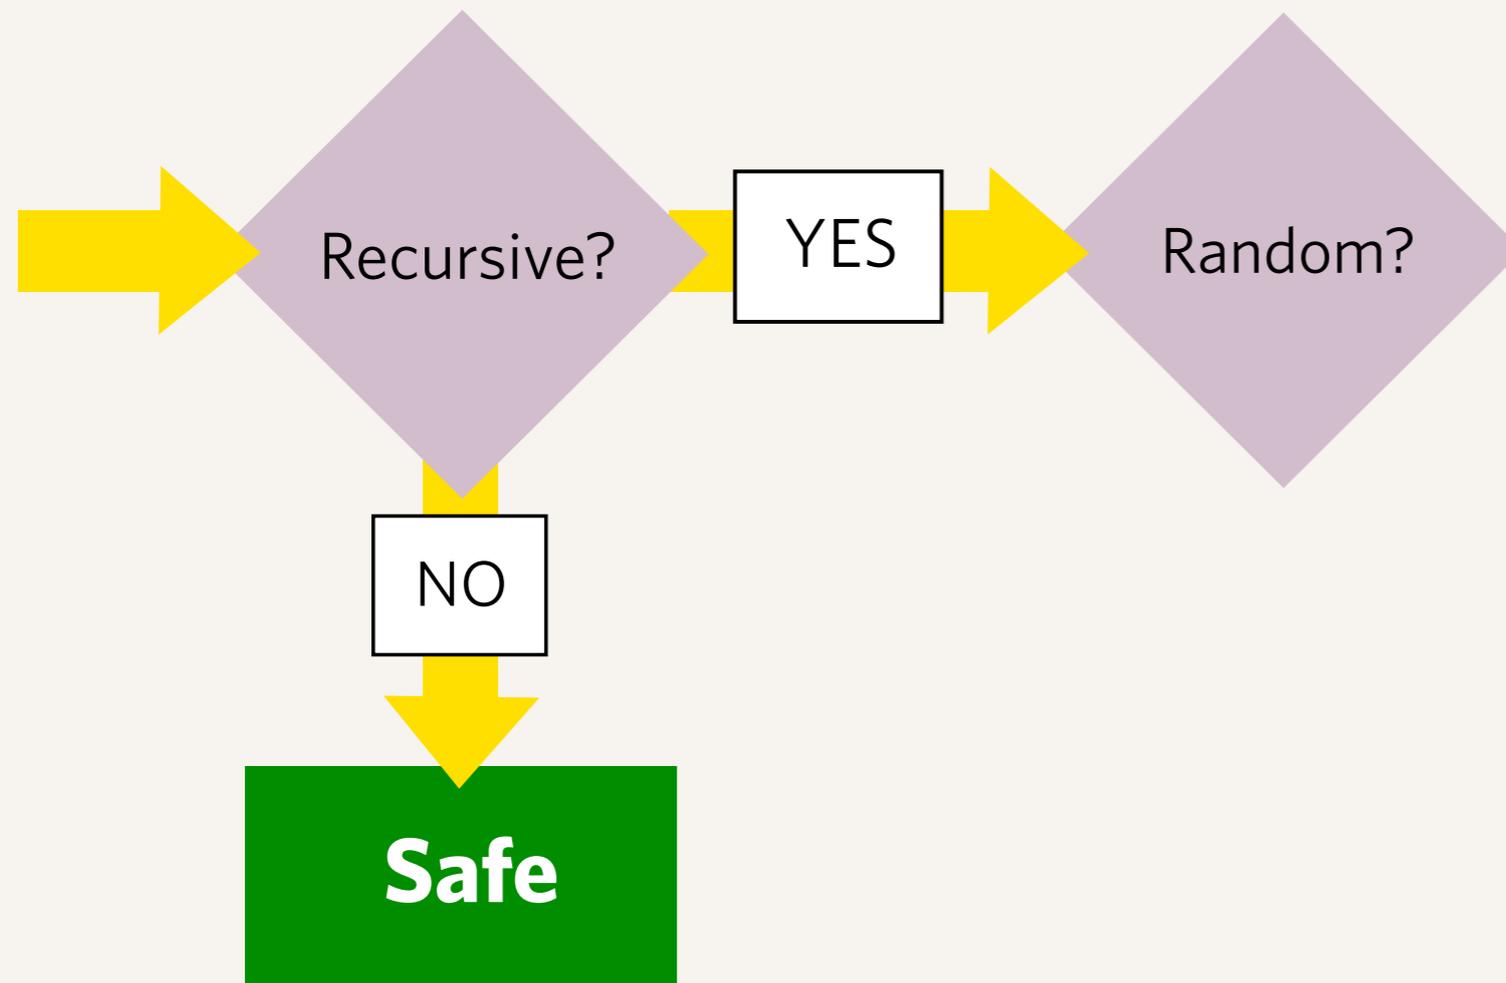

## How the tool works

- ▶ The tool checks for the two aspects that enable the attack

over **100,000** domains tested

# Work continues

- ▶ We are still working with the last remaining TLDs that are affected. Our goal is to reduce the number to zero.
- ▶ It is anticipated a ban on open recursive name servers will be instituted as a formal IANA requirement on future root zone changes.
- ▶ Work on DNSSEC, and signing the root, to facilitate a longer term solution

Thanks!
